Abstract
This paper considers the problem of building fault-tolerant shared objects when processes can crash and recover but lose their persistent state on recovery. This Diskless Crash-Recovery (DCR) model matches the way many long-lived systems are built. We show that it presents new challenges, as operations that are recorded at a quorum may not persist after some of the processes in that quorum crash and then recover.

To address this problem, we introduce the notion of crash-consistent quorums, where no recoveries happen during the quorum responses. We show that relying on crash-consistent quorums enables a recovery procedure that can recover all operations that successfully finished. Crash-consistent quorums can be easily identified using a mechanism we term the crash vector, which tracks the causal relationship between crashes, recoveries, and other operations.

We apply crash-consistent quorums and crash vectors to build two storage primitives. We give a new algorithm for multi-writer, multi-reader atomic registers in the DCR model that guarantees safety under all conditions and termination under a natural condition. It improves on the best prior protocol for this problem by requiring fewer rounds, fewer nodes to participate in the quorum, and a less restrictive liveness condition. We also present a more efficient single-writer, single-reader atomic set—a virtual stable storage abstraction. It can be used to lift any existing algorithm from the traditional Crash-Recovery model to the DCR model. We examine a specific application, state machine replication, and show that existing diskless protocols can violate their correctness guarantees, while ours offers a general and correct solution.

1 Introduction

Today’s distributed systems are key pieces of infrastructure that must remain available even though the servers that implement them are constantly failing. These systems are long-lived and must be able to tolerate nodes crashing and rejoining the system. In particular, nodes must be able to rejoin the system even after losing their disk state, a real concern for large-scale data centers where hard drive failures are a regular occurrence [7].

This paper addresses the problem of how to build recoverable shared objects even when processes lose their entire state. We consider the Diskless Crash-Recovery model: each process in the system may go down at any time; upon recovery, it loses all state it had before the crash except for its identity. However, processes can run a recovery protocol to...
recover their state before deeming themselves operational again. This model matches the way that many distributed systems are built in practice.

The Diskless Crash-Recovery model (DCR) is more challenging than the traditional Crash-Stop model (CS) or the Crash-Recovery with Stable Storage model (CRSS). The main challenge is that an invariant that holds at one process may not hold on that process’s next incarnation after recovery. This leads to the problem of unstable quorums: it is possible for a majority of processes to acknowledge a write operation, and yet processes can still subsequently lose that knowledge after crash and recovery.

We provide a general mechanism for building recoverable shared objects in the DCR model. We show that an operation can be made recoverable once it is stored by a crash-consistent quorum, which we informally define as one where no recoveries happen during the quorum responses. Crash-consistent quorums can be efficiently identified using a mechanism called the crash vector: a vector, maintained by each process, that tracks the latest known incarnation of each process. By including crash vectors in protocol messages, processes can identify the causal relationship between crash recoveries and other operations. This makes it possible to discard responses that are not part of a crash-consistent quorum. We show that this is sufficient to make storage mechanisms recoverable.

The crash-consistent quorum approach is a general strategy for making storage primitives recoverable. We give two concrete examples in this paper, both of which are always safe and guarantee liveness during periods of stability; other storage primitives are also possible:

- First, we build a multi-writer, multi-reader atomic register by extending the well-known ABD protocol [3] with crash vectors. This improves on the best prior protocol by Konwar et al. [17], RADON$^S_R$, for this problem: it requires fewer rounds (2 rather than 3), requires fewer nodes to participate in the protocol (a simple majority vs $3/4$), and has a less restrictive liveness condition.
- Second, we construct a single-writer, single-reader atomic set, which has weaker semantics yet permits a more efficient implementation, requiring only a single round of communication for writes. We refer to this algorithm as virtual stable storage, as it offers consistency semantics similar to a local disk. We show that the virtual stable storage protocol can be used to transform any protocol that operates in the traditional CS or CRSS models to one that operates in DCR.

We discuss the application of this work to state machine replication, a widely used distributed system technique. Recovering from disk failures is an important concern in practice, and recent replication protocols attempt to support recovery after complete loss of state. Surprisingly, we find that each of the three such protocols [7,16,22] can lose data. We identify a general problem: while these protocols go to great lengths to ensure that a recovering replica reconstructs the set of operations it previously processed, they fail to recover critical promises the replica has previously made, e.g., to elect a new leader. This is due to the fact that these protocols rely on unstable quorums to persist these promises. This causes nodes to break important invariants upon recovery, causing the system to violate safety properties. Our approach provides a correct, general, and efficient solution.

To summarize, this paper makes the following contributions:

- It formalizes a Diskless Crash-Recovery (DCR) failure model in a way that captures the challenges of long-lived applications (Section 3).
- It introduces the notion of crash-consistent quorums and provides two communication primitives for reading from and writing to crash-consistent quorums (Section 4).
- It presents algorithms built on top of our communications primitives for two different shared objects in the DCR model: an atomic multi-writer, multi-reader register and an
atomic single-writer, single-reader set. The former is a general purpose register which demonstrates the generality of our approach, while the latter provides a virtual stable storage interface that can be used to port any protocol in the CRSS model to one for the DCR model (Section 5).

Finally, it examines prior protocols for state machine replication in the DCR failure model and demonstrates flaws in these protocols that lead to violations of safety properties. Our two communication primitives can provide correct solutions (Section 6).

2 Background and Related Work

Static Systems. A static system comprises a fixed, finite set of processes. Fault-tolerant protocols for reliable storage for static systems have been studied extensively in the Crash-Stop (CS) failure model, where processes that fail never rejoin the system, and the Crash-Recovery with Stable Storage model (CRSS). In the latter model, processes recover with the same state after a crash. Consensus and related problems, in particular, have been studied extensively in these settings [8, 12, 30]. In CRSS, a crashed and recovered node is no different than one which was temporarily unavailable; asynchronous algorithms that tolerate lossy networks are inherently robust to these types of failures [8].

Prior work on fault-tolerant shared objects and consensus without stable storage generally requires some subset of the processes to never fail [1, 11]. Aguilera et al. [1] showed an impossibility result for a crash-recovery model: even with certain synchrony assumptions, consensus cannot be solved without at least one process that never crashes. The main differentiator between that work and this paper is that in their model, the states of processes were binary—either “up” or “down.” We overcome this limitation by adding an extra “recovering” state. As long as the number of processes which are “down” or “recovering” at any given time is bounded, certain problems can be solved even without processes that never fail.

Recently, Konwar et al. [17] presented a set of algorithms for implementing an atomic multi-writer, multi-reader (MWMR) register in a model similar to ours. We generalize and improve on this work using new primitives for crash-consistent quorums. Our techniques are applicable to other forms of shared objects as well, and our MWMR register is more efficient: it requires one fewer phase and a simple majority quorum (vs $3/4$).

Several recent practical state machine replication systems [7, 16, 22] incorporate ad hoc recovery mechanisms for nodes to recover from total disk loss. The common intuition behind these approaches is that a write to disk can be replaced with a write to a quorum of other nodes, recovering after a failure by performing a quorum read. However, we show that these protocols are not correct; they can lose data in certain failure scenarios. A more recent design, Replacement [13], provides a mechanism for replacing failed processes. Like our work and the epoch vectors in JPaxos [16], it draws on concepts like version vectors [31] and vector clocks [9] to determine the causal dependencies between replacements and other operations. We build on these techniques to provide generic communication primitives in DCR.

Dynamic Systems. In a dynamic setting, processes may leave or join the system at will. Although we consider a static system, DCR may be viewed as a dynamic system with a finite concurrency level [26], i.e., where there is a finite bound on the maximum number of processes that are simultaneously active, over all runs. Here, a recovering process without state is equivalent to a newly joined process.
Many dynamic systems implement reconfiguration protocols [2, 10, 21–24, 33]. Reconfiguration allows one to change the set of members allowed to participate in the computation. This process allows both adding new processes and removing processes from the system. Reconfiguration is a more general problem than recovery: it can be used to handle disk failure by introducing a recovering node as a new member and removing its previous incarnation. However, general reconfiguration protocols are a blunt instrument, as they must be able to handle completely changing the membership to a disjoint set of processes. As a result, these protocols are costly. Most use consensus to agree on the order of reconfigurations, which delays the processing of concurrent operations [28]. DynaStore [2] is the first proposal which does not require consensus, but reconfigurations can still delay R/W operations [28]. Smart-Merge [14] improves on DynaStore by offering a more expressive reconfiguration interface. Recovery is a special case of reconfiguration, where each recovering process replaces, and has the same identity as, a previously crashed process. As a result, it permits more efficient solutions.

Other protocols implement shared registers and other storage primitives in churn-prone systems [4–6, 15]. In these systems, processes are constantly joining and leaving the system, but at a bounded rate. These protocols remain safe only when churn remains within the specified bound, in contrast to our work which is always safe. Most of these protocols also require synchrony assumptions for correctness. However, under these assumptions they are able to provide liveness guarantees even during constant churn.

3 System Model

We begin by defining our failure model: Diskless Crash-Recovery (DCR), a variant of the classic Crash-Recovery model where processes lose their entire state upon crashing.

We consider an asynchronous distributed system which consists of a fixed set of $n$ processes, $\Pi$. Each process has a unique name (identifier) of some kind; we assume processes are numbered $1, \ldots, n$ for simplicity. Each process executes a protocol (formally, it is an I/O automaton [25]) while it is up. An execution of a protocol proceeds in discrete time steps, numbered with $N$, starting at $t = 0$. At each step, at most one process either processes an input action, processes a message, crashes, or restarts. If it crashes, the process stops receiving messages and input actions, loses its state, and is considered down. A process that is down can restart and transition back to the up state. We make the following assumptions about a process that restarts: (1) it knows it is restarting, (2) it knows its unique name and the names of the other processes in the system (i.e., this information survives crashes), and (3) it can obtain an incarnation ID that is distinct from all the ones that it previously obtained. Note that the incarnation ID need only be unique among different incarnations of a specific process, not the entire system. These are reasonable assumptions to make for real-world systems: (1) and (2) are fixed for a given deployment, and (3) can be obtained, for example, from a source of randomness or the local processor clock.

Processes are connected by an asynchronous network. Messages can be duplicated a finite number of times or reordered arbitrarily – but not modified – by the network. We assume that if an incarnation of a process remains up, sends a message, and an incarnation of the destination process stays up long enough, that message will eventually be delivered.¹

The unique incarnation ID makes it possible to distinguish different incarnations of the same process. Without unique incarnation IDs, processes are vulnerable to “replay attacks.”

¹ This model is equivalent to one in which the network can drop any message a finite number of times, with the added stipulation that processes resend messages until they are acknowledged.
Theorem 1. Any state reached by a process that has crashed, restarted, and taken steps without receiving an input action or crashing again will always be reachable by that process.

Proof. Suppose process $p$ has crashed, restarted, and taken some number of steps without crashing or receiving an input action. That is, suppose that after it restarted, $p$ received some sequence of messages, $M$. Because $p$ is an I/O automaton without access to randomness or unique incarnation IDs, anytime $p$ crashes and restarts, it restarts into the exact same state. Furthermore, if $p$ crashes, restarts, and receives the same sequence of messages, $M$, having been duplicated by the network, $p$ will always end up in the same state.

A corollary to Theorem 1 is that any protocol in the DCR model without unique incarnation IDs satisfying the safety properties of consensus—or even a simple shared object such as a register—can reach a state from which terminating states are not reachable (i.e., a state of deadlock). If all processes crash and recover before deciding a value or receiving a write, they can always return to this earlier state, so the protocol cannot safely make progress.

For simplicity of exposition, we assume that the incarnation ID increases monotonically. We explain in our technical report [27] how to eliminate this requirement.

A restarting process must recover parts of its state. To do so, it runs a distinct recovery protocol. This protocol can communicate with other processes to recover previous state. Once the recovery protocol terminates, the process declares recovery complete and resumes execution of its normal protocol. We describe a process that is up as recovering if it is running its recovery protocol and operational when it is running the initial automaton. A protocol in this model should satisfy recovery termination: a recovering process eventually becomes operational, as long as it does not crash again in the meantime. This precludes vacuous solutions where recovering process never again participate in the normal protocol.

Using a separate recovery protocol matches the design of existing protocols like View-stamped Replication [22]. Importantly, the distinction between recovering and operational allows failure bounds in terms of the number of operational processes, e.g., that fewer than half of the processes can be either down or recovering at any moment. This circumvents Aguilera et al.’s impossibility result for consensus [1], which does not make such a distinction (i.e., restarting processes are immediately considered operational).

4 Achieving Crash-Consistent Quorums

Making shared objects recoverable in the DCR model requires a new type of quorum to capture the idea of persistent, recoverable knowledge. A simple quorum does not suffice. We demonstrate the problem through a simple straw-man example, and introduce the concepts of crash-consistent quorums and crash vectors to solve the problem. We use these to build generic quorum communication and recovery primitives.

4.1 Unstable Quorums: Intuition

Consider an intentionally simple example: a fault-tolerant safe register that supports a single writer and multiple readers. A safe register [19] is the weakest form of register, as the behavior of READ operations is only defined when there are no concurrent WRITEs. We further constrain the problem by allowing the writer to only ever execute one WRITE operation. That is, the only safety requirement is that once the WRITE completes, all subsequent READs that return must return the value written.

In the Crash-Stop model, a trivial quorum protocol suffices: WRITE($val$) broadcasts $val$ and waits for acknowledgments from a quorum. Here, we consider majority quorums:
Definition 1. A quorum $Q$ is a set of processes such that $Q \in \mathcal{Q} = \{ Q : Q \in 2^{\Pi} \land |Q| > n/2 \}$.

A subsequent READ would then be implemented by reading from a quorum. The quorum intersection property (i.e., $\forall Q_1, Q_2 \in \mathcal{Q} \ Q_1 \cap Q_2 \neq \{\} \ )$ guarantees that at least one process will return val for a READ that happens after the WRITE. It is easy to extend this protocol to the CRSS model simply by having each process log val to disk before replying to a WRITE.

Could we use this same quorum protocol in our DCR model, where processes that crash recover without stable storage, by augmenting it with a recovery protocol that satisfies recovery termination? In fact, for this particular protocol, there is no recovery protocol that both guarantees the safety requirement and recovery termination – even if there is a majority of processes which are operational at any instant! In order to tolerate the crashes of a minority of processes and satisfy recovery termination, any recovery protocol must be able to proceed after communicating with only a simple majority of processes. However, if a process crashes in the middle of the WRITE procedure—after acknowledging val—it may recover before a majority of processes have received val. No recovery procedure that communicates only with this quorum of processes can cause the process to relearn val.

We term the resulting situation an unstable quorum: the WRITE operation received responses from a quorum, and yet by the time it completes there may no longer exist a majority of processes that know val. It is thus possible to form a quorum of processes that either acknowledged val but then lost it during recovery, or never received the write request (delayed by the network). A subsequent READ could fail by reading from such a quorum.

Although this is a simple example, many important systems suffer from precisely this problem of unstable quorums. We show in Section 6 that essentially this scenario can cause three different state machine replication protocols to lose important pieces of state.

4.2 Crash-Consistent Quorums

We can avoid this problem – both for the straw-man problem above and in the general case – by relying not just on simple quorums of responses but crash-consistent ones.

Crash Consistency. We informally define a crash-consistent quorum to be one where no recoveries of processes in the quorum happen during the quorum responses. More precisely:

Definition 2. Let $\mathcal{E}$ be the set of all events in an execution. A set of events, $E \subseteq \mathcal{E}$, is crash-consistent if $\forall e_1, e_2 \in E$ there is no $e_3 \in \mathcal{E}$ that takes place at a later incarnation of the same process as $e_1$ such that $e_3 \rightarrow e_2$. Here, $\rightarrow$ represents Lamport’s happens-before relation [18].

In Section 4.3, we show how to build recoverable primitives using crash-consistent quorums, in which all quorum replies (i.e. the message send events at a quorum) are crash-consistent.

Crash Vectors. How does a process acquire a crash-consistent quorum of responses? The mechanism that allows us to ensure a crash-consistent quorum is the crash vector. This is a vector that contains, for each process, its latest known incarnation ID. Like a version vector, processes attach their crash vector to the relevant protocol messages and use incoming messages to update their crash vector. The crash vector thus tracks the causal relationship between crash recoveries and other operations. When acquiring a quorum on a WRITE operation, we check whether any of the crash vectors are inconsistent with each other, indicating that a recovery may have happened concurrently with one of the responses. We
then discard any responses from previous incarnations of the recovering process, ensuring a crash-consistent quorum, and thus avoiding the aforementioned problem.

4.3 Communication Primitives in DCR

We now describe in detail two generic quorum communication primitives, one of which acquires a crash-consistent quorum, as well as a generic recovery procedure. These primitives require their users to implement an abstract interface: READ-STATE, which returns a representation of the state of the shared object; UPDATE-STATE, which alters the current state with a specific value; and REBUILD-STATE, which is called during recovery and takes a set of state representations and combines them.

The ACQUIRE-QUORUM primitive writes a value to a crash-consistent quorum and returns the latest state. The READ-QUORUM primitive returns a fresh—but possibly inconsistent—snapshot of the state as maintained at a quorum of processes. If ACQUIRE-QUORUM(val) succeeds, then any subsequent READ-QUORUM will return at least one response from a process that knows (i.e., has previously updated its state with) val.

The detailed protocol implementing the two primitives and the recovery procedure is presented as pseudo-code in Algorithm 1. We present the algorithm using a modified I/O automaton notation. In our protocol, procedures are input actions that can be invoked at any time (e.g., in a higher level protocol); functions are simple methods; and upon clauses specify how processes handle external events (i.e., messages, system initialization, and recovery). We use guards to prevent actions from being activated under certain conditions. If the guard of a message handler or procedure is not satisfied, no action is taken, and the message is not consumed (i.e., it remains in the network undelivered).

Each of the \( n \) process in \( \Pi \) maintains a crash vector, \( v \), with one entry for each process in the system. Entry \( i \) in this vector tracks the latest known incarnation ID of process \( i \). During an incarnation, a process numbers its acquire and read messages using the local variable \( c \) to match messages with replies. When a process recovers, it gets a new value from its local, monotonic clock and updates its incarnation ID in its own vector. When the recovery procedure ends, the process becomes operational and signals this through the op flag. A process’s crash vector is updated whenever a process learns about a newer incarnation of another process. Crash vectors are partially ordered, and a join operation, denoted \( \sqcup \), is defined over vectors, where \( (v_1 \sqcup v_2)[i] = \max(v_1[i], v_2[i]) \). Initially, each process’s crash vector is \([\bot, \ldots, \bot]\), where \( \bot \) is some value smaller than any incarnation ID.

The ACQUIRE-QUORUM function handles both writing values and recovering. ACQUIRE-QUORUM ensures the persistence of both the process’s current crash vector—in particular the process’s own incarnation ID in the vector—as well as the value to be written, \( val \). It provides these guarantees by collecting responses from a quorum of processes and ensuring that those responses are crash-consistent. It uses crash vectors to detect when any process that previously replied could have crashed and thus could have “forgotten” the written value.

4.4 Correctness

We show that our primitives provide the same safety properties as writing and reading to simple quorums in the Crash-Stop model. First, we formally define quorum knowledge in the DCR context.

Definition 3 (Stable Properties). A predicate on the history of an incarnation of a process (i.e., the sequence of events it has processed) is a stable property if it is monotonic (i.e., \( X \) being true of history \( h \) implies that \( X \) is true of any history with \( h \) as a prefix).
Recovering Shared Objects Without Stable Storage

</tbody>
</table>

Definition 4. If stable property $X$ is true of some incarnation of a process, $p$, we say that incarnation of $p$ knows $X$.

Definition 5 (Quorum Knowledge). We say that a quorum $Q$ knows stable property $X$ if, for all processes $p \in Q$, one of the following holds: (1) $p$ is DOWN, (2) $p$ is OPERATIONAL and knows $X$, or (3) $p$ is RECOVERING and either already knows $X$ or will know $X$ if and when it finishes recovery.

In our analysis of Algorithm 1, we are concerned with knowledge of two types of stable properties: knowledge of values and knowledge of incarnation IDs. An incarnation of a process knows value $val$ if it has either executed Update-State($val$) or executed Rebuild-State with an Acquire-Rep message in the reply set sent by a process which knew $val$. Knowledge
of a process’s incarnation ID, \( i \), is the stable property of having an entry in a crash vector for that process greater than or equal to \( i \).

Next, we define crash-consistency on \textsc{acquire-rep} messages with crash vectors.

\textbf{Definition 6 (Crash Consistency).} A set of \textsc{acquire-rep} messages \( R \) is crash-consistent if \( \forall s_1, s_2 \in R. s_1.v[s_2.f] \leq s_2.v[s_2.f] \).

Note that Definition 6, phrased in terms of crash vectors, is equivalent to the sending events of the \textsc{acquire-rep} messages being crash-consistent according to Definition 2.

\textbf{Definition 7 (Quorum Promise).} We say that a crash-consistent set of \textsc{acquire-rep} messages constitutes a quorum promise for stable property \( X \) if the set of senders of those messages is a quorum, and each sender knew \( X \) when it sent the message.

\textbf{Definition 8.} If process \( p \) sent one of the \textsc{acquire-rep} message belonging to a quorum promise received by some process, we say that \( p \) participated in that quorum promise.

The post-condition of the loop on line 53 guarantees the crash-consistency of the reply set by discarding any inconsistent messages; the next loop guarantees that there is at most one message from each process in the reply set. Therefore, the termination of \textsc{Acquire-Quorum} (line 10) implies that the process has received a quorum promise showing that \( val \) was written and that every participant had a crash vector greater than or equal to its own vector when it sent the \textsc{acquire} message. This implies that whenever a process finishes recovery, it must have received a quorum promise showing that the participants in its recovery had that process’s latest incarnation ID in their crash vectors.

Unlike having a stable property, that a process participated in a quorum promise holds across failures and recoveries. That is, we say that a process, not a specific incarnation of that process, participated in a quorum promise. Also note that only operational processes ever participate in a quorum promise, guaranteed by the guard on the \textsc{acquire} message handler.

4.4.1 Safety

Finally, we are ready to state the main safety properties of our generic read/write primitives.

\textbf{Theorem 2 (Persistence of Quorum Knowledge).} If at time \( t \), some quorum, \( Q \), knows stable property \( X \), then for all times \( t' \geq t \), \( Q \) knows \( X \).

\textbf{Proof.} We prove by strong induction on \( t' \) that the following invariant, \( I \), holds for all \( t' \geq t \): For all \( p \) in \( Q \): (1) \( p \) is operational and knows \( X \), (2) \( p \) is recovering, or (3) \( p \) is down. In the base case at time \( t \), \( Q \) knows \( X \) by assumption, so \( I \) holds.

Now, assuming \( I \) holds at all times \( t' - 1 \geq t \), we show that \( I \) holds at time \( t' \). The only step any process \( p \) in \( Q \) could take to falsify \( I \) is finishing recovery. If recovery began at or before time \( t \), then because \( Q \) knew \( X \), \( p \) must know \( X \) now that it has finished recovering. Otherwise, if it began after time \( t \), then \( p \) must have received some set of \textsc{acquire-rep} messages from a quorum, all of which were sent after time \( t \). By quorum intersection, one of these messages must have come from some process in \( Q \). Call this process \( q \). Since \( q \)'s \textsc{acquire-rep} message, \( m \), was sent after time \( t \) and before \( t' \), by the induction hypothesis, \( q \) must have known \( X \) when it sent \( m \). Therefore, \( p \) must know \( X \) upon finishing recovery since it updates its crash vector and rebuilds its state using \( m \).

Since \( I \) holds for all times \( t' \geq t \), this implies the theorem.

\hfill \Box
Theorem 3 (Acquisition of Quorum Knowledge). If process \( p \) receives a quorum promise for stable property \( X \) from quorum \( Q \), then \( Q \) knows \( X \).

Proof. We again prove this theorem by (strong) induction, showing that the following invariant, \( I \), holds for all times, \( t \):

1. If a process receives a quorum promise for stable property \( X \) from quorum \( Q \), then \( Q \) knows \( X \).
2. If process \( p \) ever participated in a quorum promise for \( X \) at or before time \( t \), and \( p \) is operational, then \( p \) knows \( X \).

\( I \) holds vacuously at \( t = 0 \). We show that if \( I \) holds at time \( t - 1 \), it holds at time \( t \):

First, we consider part 1 of \( I \). If \( p \) has received a quorum promise, \( R \), from quorum \( Q \) for \( X \), then because \( R \) is crash-consistent, we know that \textit{at the time they participated in} \( R \) no process in \( Q \) had participated in the recovery of any later incarnation of any other process in \( Q \) than the one that participated in \( R \). If they had, then by the induction hypothesis, such a process would have known the recovered process’s new incarnation ID when it participated in \( R \), and \( R \) would not have been crash-consistent.

Given that fact, we will use a secondary induction to show that for all times, \( t' \), all of the processes in \( Q \) either: (1) haven’t yet participated in \( R \), (2) are \textit{down}, (3) are \textit{recovering}, or (4) are \textit{operational} and know \( X \). In the base case, no process in \( Q \) has yet participated in \( R \). For the inductive step, note that the only step any process \( q \) could take that would falsify our invariant is transitioning from \textit{recovering} to \textit{operational} after having participated in \( R \). If \( q \) finished recovering, it must have received a quorum promise showing that the senders knew its new incarnation ID. By quorum intersection, at least one of these came from some process \( r \in Q \). We already know \( r \) couldn’t have participated in \( q \)'s recovery before participating in \( R \). So by the induction hypothesis, \( r \) knew \( X \) at the time it participated in \( q \)'s recovery. Because knowledge of values and incarnation IDs is transferred through \textit{acquire-rep} messages, \( q \) knows \( X \), completing this secondary induction.

Finally, we know that since \( p \) has received \( R \) at time \( t \), all of the process in \( Q \) have already participated in \( R \), so all of the processes in \( Q \) are either \textit{down}, \textit{recovering} (and will know \( X \) upon finishing recovery), or are \textit{operational} and know \( X \). Therefore, \( Q \) knows \( X \), and this completes the proof that part 1 of \( I \) holds at time \( t \).

Now, we consider part 2 of \( I \). Suppose, for the sake of contradiction, that \( p \) is \textit{operational} at time \( t \) and doesn’t know \( X \), but participated in quorum promise \( R \) for \( X \) at or before time \( t \). Let \( Q \) be the set of processes participating in \( R \). Since \( p \) does not know \( X \), \( p \) must have crashed and recovered since participating in \( R \). Consider \( p \)'s most recent recovery, and let the quorum promise it received showing that the senders knew \( p \)'s new incarnation ID (or a greater one) be \( R' \). Let the set of participants in \( R' \) be \( Q' \). By quorum intersection, there exists some \( r \in Q \cap Q' \).

It must be the case that \( r \) participated in \( R' \) before \( R \); otherwise by induction, when \( r \) participated in \( R' \), it would have known \( X \), and then transferred that knowledge to the current incarnation of \( p \) (at time \( t \)). \( r \) couldn’t have participated in \( R \) before time \( t \), because then by part 2 of \( I \), it would have known \( p \)'s latest incarnation ID when participating in \( R \), violating the consistency of \( R \). However, \( r \) cannot participate in \( R \) at or after time \( t \), either. Because \( p \) has received a quorum promise for its new incarnation ID at or before time \( t \), by part 1 of \( I \), \( Q' \) knows \( p \)'s new incarnation ID. By Theorem 2, \( Q' \) continues to know this at all later times. Because \( r \in Q' \), it must know \( p \)'s incarnation ID, and thus cannot participate in \( R \) without violating its crash-consistency. This contradicts the fact that \( r \) participates in \( R \) and completes the proof that part 2 holds at time \( t \). ◀
Since \textsc{Acquire-Quorum}(val) obtains a quorum promise for val, Theorem 3 implies quorum knowledge of val, and Theorem 2 shows that this knowledge will persist for all future time, subsequent \textsc{Acquire-Quorum} and \textsc{Read-Quorum} will get a response from a process which knows val.

4.4.2 Liveness

\textsc{Acquire-Quorum} and \textsc{Read-Quorum} terminate if there is some quorum of processes that all remain operational for a sufficient period of time.\footnote{We assume that the application-provided \textsc{Read-State}, \textsc{Update-State}, and \textsc{Rebuild-State} functions execute entirely locally and do not block.} This is easy to see since a writing or recovering process will eventually get an \textsc{Acquire-Rep} from each of these operational processes, and those replies must be crash-consistent. Note that the termination of \textsc{Acquire-Quorum} implies the termination of the recovery procedure, \textsc{Recover}. Therefore, the same liveness conditions are required for \textsc{Acquire-Quorum} and for recovery termination.

We define a sufficient liveness condition, LC, below. It is a slightly weaker version of the network stability condition \(N_2\) from \cite{17}: the period in which processes must remain operational is shorter.

\begin{definition}[Liveness Condition (LC)] Consider a process \(p\) executing either the \textsc{Acquire-Quorum} or \textsc{Read-Quorum} function, \(\phi\), and consider the following statements: (1) There exists a quorum of processes, \(Q\), all of which consume their respective messages sent from \(\phi\). (2) Every process in \(Q\) either (a) remains operational during the interval \([T_1, T_2]\), where \(T_1\) is the point in time at which \(\phi\) was invoked and \(T_2\) the earliest point in time at which \(p\) completes the consumption of all the responses sent by the processes in \(Q\) or (b) becomes down and remains down during the same interval after \(p\) consumed its response. If these two statements are true for every invocation of a \textsc{Acquire-Quorum} or \textsc{Read-Quorum} function, then we say that LC is satisfied.
\end{definition}

Our protocol implementing the group communication primitives is live if LC is satisfied. For LC to be satisfied, it is necessary that at most a minority of processes are down at any given time. Otherwise, no process can ever receive replies from a quorum again.

5 Recoverable Shared Objects in DCR

In this section we demonstrate the benefits of our quorum communication primitives for DCR: generality and efficiency. We present protocols for two different shared objects: a multi-writer, multi-reader (MWMR) atomic register and a single-writer, single-reader (SWSR) atomic set. In both protocols, \textsc{Read} and \textsc{Write} are intended to be invoked serially.

The first protocol implements a shared, fault-tolerant MWMR atomic register in DCR. It is more efficient and has better liveness conditions than prior work. The second protocol implements a weaker abstraction—a shared, fault-tolerant SWSR atomic set. We use this set as a basic storage primitive to provide processes with access to their own virtual stable storage (VSS), an emulation of a local disk. This enables easy migration of protocols to DCR.

5.1 Multi-writer, Multi-reader Atomic Register

We present a protocol for implementing a fault-tolerant, recoverable multi-writer, multi-reader (MWMR) atomic register in DCR, which guarantees the linearizability of Reads.
and Writes [19]. Our protocol is similar to the ABD protocol [3] but augments it with a recovery procedure. Its pseudo-code is presented in Algorithm 2. Timestamps are used for version control, as in the original protocol. A timestamp is defined as a triple \((z, i, v[i])\), where \(z \in \mathbb{N}\), \(i \in [1..n]\) is the ID of the writing process, and \(v[i]\) is the incarnation ID of that process. Timestamps are ordered lexicographically. By replacing each quorum write phase in the original protocol with our Acquire-Quorum function and each quorum read phase with Read-Quorum, we guarantee that every successful write phase is visible to subsequent read phases, despite concurrent crashes and recoveries, thus preserving safety in DCR. The Rebuild-State function reconstructs a value of the register at least as new as the one of the last successful write that finished before the process crashed.

**Discussion.** The most recent protocol for fault-tolerant, recoverable, MWMR atomic registers is RADON [17]. The always-safe version of RADON, \(\text{RADON}^{(S)}\), introduces an additional communication phase after each quorum write to check whether any of the processes that acknowledged the write crashed in the meantime. This increases the latency of both the Read and Write procedures. Also, our liveness conditions are weaker: our protocol is live if any majority of processes do not crash for a sufficient period of time, while \(\text{RADON}^{(S)}\) requires a supermajority \((3/4)\) of processes to not crash.

### 5.2 Virtual Stable Storage

Algorithm 3 presents a protocol for a fault-tolerant, recoverable, SWSR set, where the reader is the same as the writer. It guarantees that the values written by completed Writes and those returned in Reads are returned in subsequent Reads. Given the group communication primitives, its implementation is straightforward; the only additional detail is that values read during recovery should be written back to ensure atomicity (line 17).

**Discussion.** We can use this set to provide a virtual stable storage abstraction. It is well known that any correct protocol in CS can be transformed into a correct protocol in the
CRSS model by having processes write every message they receive (or the analogous state update) to their local disk before sending a reply. By equipping each process with VSS, any correct protocol in the CRSS model can then be converted into a safe protocol in the DCR model, wherein processes write to crash-consistent quorums instead of stable storage.

6 Recoverable Replicated State Machines in DCR

We further extend our study of DCR to another specific problem: state machine replication (SMR). SMR is a classic approach for building fault-tolerant services [18,32] that calls for the service to be modeled as a deterministic state machine, replicated over a group of replicas. System correctness requires each replica to execute the same set of operations in the same order, even as replicas and network links fail. This is typically achieved using a consensus-based replication protocol such as Multi-Paxos [20] or Viewstamped Replication [22,29] to establish a global order of client requests.

We examined three diskless recovery protocols for SMR: Viewstamped Replication [22], Paxos Made Live [7], and JPaxos [16]. We found that each of these protocols suffers from the problem illustrated in the example at the beginning of Section 4: they use regular quorums of responses (instead of crash-consistent ones) when persisting critical data, which could violate their invariants. This can lead to operations being lost, or different operations being executed at different replicas, both serious correctness violations. We provide here brief explanations of the problems in each of these protocols. For more details on how the protocols work and complete traces, see our technical report [27].

**Viewstamped Replication** [29] is the first consensus-based SMR protocol. The original version of the protocol requires a single write to disk, during a view change. A recent VR variant [22] replaces the write to disk with a write to a quorum of replicas, in an attempt to eliminate the necessity for disks. However, it uses simple quorum responses, allowing the recovering replica to violate an important invariant: once a replica committed to take part in a new view, it will never operate in a lower view. As a result, an operation can complete successfully and then be lost after a view change.

**Paxos Made Live** [7] is Google’s Multi-Paxos implementation. To handle corrupted disks, it lets a replica rejoin the system without its previous state and runs an (unspecified) recovery protocol to restore the application state. The replica must then wait to observe a full instance of successful consensus before participating. This successfully prevents the
recovery, a replica from accepting multiple values for the same instance (e.g., one before and one after the 
crash). However, it does not prevent the replica from sending different promises (i.e., leader 
change commitments) to potential new leaders, which can lead to a new leader deciding a 
new value for a prior successful instance of consensus.

JPaxos [16], a hybrid of Multi-Paxos and VR, provides a variety of deployment options, 
including a diskless one. Nodes in JPaxos maintain an epoch vector that tracks which nodes 
have crashed and recovered to discard lost promises made by prior incarnations of recovered 
nodes. However, like VR and PML, certain failures during node recovery can cause the 
system to lose state and violate safety properties.

All of these protocols can be correctly migrated to DCR, with little effort, using VSS 
write operations, as explained in Section 5.2. This approach is straightforward, efficient, and 
requires no invasive protocol modifications.

7 Conclusion

This paper examined the Diskless Crash-Recovery model, where process can crash and recover 
but lose their state. We show how to provide persistence guarantees in this model using 
new quorum primitives that write to and read from crash-consistent quorums. These general 
primitives allow us to construct shared objects in the DCR model. In particular, we show a 
MWMR atomic register protocol requiring fewer communication rounds and weaker liveness 
assumptions than the best prior work. We also build a SWSR atomic set that can be used 
to provide each process with virtual stable storage, which can be used to easily migrate any 
protocol from traditional Crash-Recovery models to DCR.

Acknowledgments. We thank Marcos K. Aguilera for his comments on early drafts of this 
work, as well as Irene Zhang, the anonymous reviewers, and Jennifer L. Welch for their helpful 
feedback. This material is based upon work supported by the National Science Foundation 
under award CNS-1615102 and a Graduate Research Fellowship, and by gifts from Google
