We present a study on conditional maximum likelihood (CML) estimation of probability models by means of a well known technique that generalizes the Baum-Eagon inequality [1] from polynomials to rational functions. The main advantage of the rational function growth transform (RFGT) method [5] is that it keeps the model parameter values — probabilities — properly normalized at each iteration. As a case study we apply the technique to discriminatively train a Naive Bayes (NB) classifier; the same procedure is at the basis of discriminative training of HMMs in speech recognition [6].

The NB model trained under the maximum likelihood (ML) and CML criteria, respectively, is used on a text classification problem. Smoothing is found to be a key component in increasing the classification accuracy. A simple modification of the algorithm increases the convergence speed significantly — as measured by likelihood and classification accuracy increase per iteration — over a straightforward implementation of RFGT. The model trained under the CML criterion achieves a relative improvement of 40% in classification accuracy over its ML counterpart [3].

The NB model can also be re-parameterized as a standard conditional exponential model encountered in maximum entropy (MaxEnt) estimation [2]. Although the two parameterizations are in principle equivalent and should lead to the same model when trained under CML, the conditional exponential model estimated using improved iterative scaling (IIS) and smoothing with a Gaussian prior [4] outperforms the smoothed NB model estimated using RFGT when evaluated in terms of classification accuracy.

Conditional Naive Bayes Models In many practical applications one seeks to model a conditional probability \( P(y|x), y \in \mathcal{Y}, x \in \mathcal{X} \). We will restrict our attention to using features that are binary valued indicator functions \( f(x) : \mathcal{X} \to \{0, 1\}, f_k(x) = 1 - f(x) \). Let \( \mathcal{F} = \{ f_k, k = 1 \ldots F \} \) be the set of features chosen for building a particular model \( P(y|x) \). Assuming a NB model for the feature vector and the predicted variable \((f(x), y)\) the conditional probability \( P(y|x) \) can be calculated as:

\[
P(y|x; \theta) = Z(x; \theta)^{-1} \prod_{k=1}^{F} \theta_{y} f_k(x) \prod_{y} \theta_{ky}^{-1}
\]

where: \( \theta_{y} \geq 0, \forall y \in \mathcal{Y}, \sum_{y} \theta_{y} = 1; \theta_{ky} \geq 0, \theta_{ky} + \theta_{ky} = 1, \forall k = 1 \ldots F, y \in \mathcal{Y} \) and \( Z(x; \theta)^{-1} = \sum_{y} P(f(x), y) \) is a normalization term.

Rational Function Growth Transform for CML Estimation of Naive Bayes Models It is desirable to estimate the model parameters \( \hat{\theta} = \{ \theta_y, \theta_{ky}, \theta_{ky}, \forall y \text{ and } k \} \) such that the conditional likelihood \( H(T; \hat{\theta}) = \prod_{j=1}^{T} P(y_j|x_j) \) assigned by the model to a set of training samples \( T = \{(x_1, y_1), \ldots (x_T, y_T)\} \) is maximized: \( \hat{\theta}^* = \arg \max_{\theta} H(T; \theta) \). It is easy to note that \( H(T; \theta) \) is a ratio of two polynomials with real coefficients, each defined over a set \( \times \) of probability distributions:

\[
\times = \{ \hat{\theta} : \theta_y \geq 0, \forall y \in \mathcal{Y} \text{ and } \sum_{y} \theta_{y} = 1; \theta_{ky} \geq 0, \theta_{ky} \geq 0 \text{ and } \theta_{ky} + \theta_{ky} = 1, \forall y \in \mathcal{Y} \}
\]

Following the development in [5] one can iteratively estimate the model parameters using a growth transform for rational functions on the domain \( \times \). The re-estimation equations take the form:

\[
\hat{\theta}_y = N^{-1} \theta_y \left( \frac{\partial \log H(T; \theta)}{\partial \theta_y} + C_\theta \right)
\]

\[
N = C_{\theta} + \sum_y \theta_y \frac{\partial \log H(T; \theta)}{\partial \theta_y}
\]

\[
\hat{\theta}_{ky} = N^{-1} \theta_{ky} \left( \frac{\partial \log H(T; \theta)}{\partial \theta_{ky}} + C_{\theta} \right)
\]

\[
N_y = C_{\theta} + \theta_{ky} \frac{\partial \log H(T; \theta)}{\partial \theta_{ky}} + \vartheta_{ky} \frac{\partial \log H(T; \theta)}{\partial \vartheta_{ky}}
\]

where \( C_{\theta} > 0 \) is chosen such that, with \( \epsilon > 0 \) suitably chosen (see [5] and [3] for details) we have:

\[
\frac{\partial \log H(T; \theta)}{\partial \theta_y} + C_{\theta} > \epsilon, \forall y
\]

\[
\frac{\partial \log H(T; \theta)}{\partial \theta_{ky}} + C_{\theta} > \epsilon, \forall k \text{ and } y
\]

\[
\frac{\partial \log H(T; \theta)}{\partial \vartheta_{ky}} + C_{\theta} > \epsilon, \forall k \text{ and } y
\]

**Equivalence with Exponential Models**

Setting: \( f_k(x, y) = f_k(x) \cdot \delta(y); \lambda_{ky} = \log(\theta_{ky}) \);

\( \lambda_{xy} = \log(\theta_y \cdot \prod_{k=1}^{F} \theta_{ky}) \) and \( f_0(x, y) = f_0(y) \) in Eqn. (1) we obtain the familiar log-linear model arrived at in maximum entropy probability estimation [2]:

\[
P(y|x; \lambda) = Z(x; \lambda)^{-1} \cdot \exp \left( \sum_{k=0}^{F} \lambda_{ky} f_k(x, y) \right)
\]

where \( \lambda_{ky} \) are free real-valued parameters and \( Z(x; \lambda) \) a normalization term.
