ALTER: Exploiting Breakable Dependences for Parallelization

Abstract

For decades, compilers have relied on dependence analysis to determine the legality of their transformations. While this conservative approach has enabled many robust optimizations, when it comes to parallelization there are many opportunities that can only be exploited by changing or re-ordering the dependences in the program.

This paper presents ALTER: a system for identifying and enforcing parallelism that violates certain dependences while preserving overall program functionality. Based on programmer annotations, ALTER exploits new parallelism in loops by reordering iterations or allowing stale reads. ALTER can also infer which annotations are likely to benefit the program by using a test-driven framework.

Our evaluation of ALTER demonstrates that it uncovers parallelism that is beyond the reach of existing static and dynamic tools. Across a selection of 12 performance-intensive loops, 9 of which have loop-carried dependences, ALTER obtains an average speedup of 2.0x on 4 cores.

1. Introduction

Throughout the long history of research on automatic parallelization, much of the progress has been driven by the compiler’s ability to accurately detect the dependences between different parts of the program. Such dependence analysis has evolved greatly over the years, encompassing representations such as direction vectors, distance vectors, and affine dependences [11] as well as techniques such as array dataflow analysis [25], interprocedural dependence analysis [7] and constraint-based dependence analysis [31]. The precision of dependence analysis has also depended on improvements in alias analysis, shape analysis, and escape analysis, which each have their own rich history.

Despite the tremendous progress in dependence analysis, in practice it remains commonplace for an incomplete understanding of the program’s dependences to prohibit seemingly simple transformations, such as parallelization of DOALL loops. There are three fundamental limitations that prevent any dependence analysis from fully solving the problem of automatic parallelization. First, as the general case of dependence analysis is undecidable [34], any static analysis must be conservative in over-approximating the program dependences, thereby under-approximating the opportunities for parallelization. A related problem is that of induction variable analysis: certain dependences can be soundly eliminated via conversion to a closed-form function of the loop index, but complex induction variables (such as iterators through a linked list) are difficult to detect automatically.

Second, even if dependences are precisely inferred (e.g., using dynamic dependence analysis [39] or speculative parallelization [10, 13, 19, 27, 32, 35, 40]), there remain many programs in which memory dependences are accidental artifacts of the implementation and should not inhibit parallelization. For example, it has been shown that in many performance-intensive loops, the only serializing dependences are due to calls to the memory allocator, which can be freely reordered without impacting correctness [5, 37]. Similar dependences are due to benign references to uninitialized data structures, maintenance or output of unordered debugging information, and other patterns [37]. Only by allowing the compiler to reorder or ignore such dependences is it possible to extract parallelism from many programs.

Third, there are many cases in which broken data dependences do change the course of a program’s execution, but the algorithm employed is robust to the changes and arrives at an acceptable output anyway. A simple example is the chain of dependences implied by successive calls to a random number generator, which has the potential to serialize many loops. However, in algorithms such as simulated annealing or monte-carlo simulation, any ordering of the calls is permissible so long as each result is random [5, 37]. A more subtle example is that of successive relaxation algorithms, in which the solution is iteratively improved in a monotonic fashion and broken dependences (such as stale reads) may enable parallelism at the expense of a slight increase in convergence time.

In this paper, we make three contributions towards enabling parallelization of programs that are beyond the reach of dependence analysis. First, we propose a new execution model, StaleReads, which enables iterations of a loop to execute in parallel by allowing stale reads from a consistent snapshot of the global memory. This model enforces a well-known guarantee called snapshot isolation that is frequently employed in the database community as a permissive and high-performance policy for transactional commit. However, while other concepts from databases have impacted programming languages via transactional memory, we are unaware of any exploration or implementation of snapshot isolation as a general-purpose mechanism for loop parallelization. In addition to the basic model, we also offer support for reductions, in which commutative and associative updates to specific variables are merged upon completion of each iteration. We demonstrate that snapshot isolation exposes useful parallelism in several algorithms, in particular for convergence algorithms that are robust to stale reads (as described in the previous paragraph).

Our second contribution is a general framework, ALTER, for specifying dependences that don’t matter and leveraging that information in a parallel runtime system. Using ALTER, the programmer annotates each loop with one of two permissive execution policies. In addition to StaleReads, ALTER supports unordered execution of the loop iterations; this corresponds to the database notion of conflict serializability and may break the original dependences so long as execution is consistent with some serial ordering of the iterations. Annotations are also used to declare reduction variables, as described above. Given the annotations, ALTER implements the desired parallelism using a deterministic fork-join model. Each loop iteration (or chunk of iterations) is treated as a transaction, executing in an isolated process and committing with a different policy depending on the model of parallelism. The implementation of ALTER relies on a novel multi-process memory allocator as well as a custom collections class that enables iterators over linked data structures to be recognized as induction variables.

Our third contribution is a practical methodology that leverages ALTER to discover and exploit parallelism. As the ALTER annotations may change the local behavior of a program, it is intractable to
This section illustrates two examples where breaking dependences (Section 8) and conclusions (Section 9).

A numerical algorithm to solve a system of linear equations of the form $Ax = b$. The for loop is annotated by ALTER to indicate that the iterations are likely to tolerate stale reads. Parallelization using the ALTER compiler and runtime system gives a speedup of 1.70x on 4 cores (for a sparse matrix $A$ with 20,000 elements).

Infer or verify them using a sound static analysis. However, to assist programmers in exploring the space of potential parallelizations, we propose a test-driven framework that evaluates each possible annotation on each loop in the program and conveys to the programmer the set of annotations that preserve the program output across a test suite. This dynamic analysis, while unsound, can be used to infer likely annotations that are subsequently validated by the programmer. The test-driven framework benefits greatly from ALTER’s deterministic execution model, as each test needs to be executed only once. Using this end-to-end methodology, we apply ALTER to assist with parallelization of a set of benchmarks, drawn from Berkeley’s parallel dwarfs as well as the STAMP suite.

The rest of this paper is organized as follows. We start with a motivating example for the violation of program dependences during loop parallelization (Section 2). We proceed to describe the ALTER annotation language (Section 3), the implementation of the ALTER compiler and runtime system (Section 4), the annotation inference algorithm (Section 5) and the usage scenarios in which ALTER could be applied (Section 6). We then present our experimental evaluation (Section 7) before wrapping up with related work (Section 8) and conclusions (Section 9).

2. Motivating Examples

This section illustrates two examples where breaking dependences enables parallel execution while preserving the high-level functionality.

The first example (see Figure 1) is a numerical algorithm to solve a system of linear equations of the form $Ax = b$, where $A$ is an $n \times n$ input matrix, $b$ is an input vector of $n$ elements and $x$ is the solution vector of $n$ unknown elements. This algorithm often forms the kernel for solving partial differential equations. The algorithm has two loops, an outer while loop that checks for convergence and an inner for loop that re-calculates each element of $XVector$ based on the values of the other elements. The inner loop has a tight dependence chain as the $XVector$ element written to in one iteration is read in every subsequent iteration. Thus, the only possible way to parallelize this loop is to violate sequential semantics by not enforcing some of the true dependences.

Based on conformance to test cases, ALTER suggests that the inner loop can be parallelized under the $StaleReads$ model. While some of the values read from $XVector$ will be stale, the algorithm

```bash
while (CheckConvergence(AMatrix, XVector, BVector, dimA) == 0) {
    tripCount++; // StaleReads
    for (int i = 0; i < dimA; i++) {
        sum = 0;
        // scalarProduct reads all of XVector
        sum = AMatrix->scalarProduct(i, XVector);
        sum -= (AMatrix->getElement(i, i) * XVector[i]);
        // write to XVector[i]
        XVector[i] = (BVector[i] - sum) / AMatrix->getElement(1, i);
    }
}
```

Figure 1. Iterative algorithm to solve a system of linear equations of the form $Ax = b$. The for loop is annotated by ALTER to indicate that the iterations are likely to tolerate stale reads. Parallelization using the ALTER compiler and runtime system gives a speedup of 1.70x on 4 cores.

The second example (see Figure 2) shows the main loop of the K-means clustering algorithm. ALTER suggests the OutOfOrder and $StaleReads$ annotations along the for loop, in combination with an additive reduction on the variable $delta$ (which is used to determine the termination of the overall algorithm). Parallelizing this algorithm using $StaleReads$ gives a speedup of 1.71x on 4 cores.

```bash
new_centers_len[index] = nfeatures + 1;
for (j = 0; j < nfeatures; j++) {
    new_centers[index][j] = new_centers_len[index] + feature[i][j];
}
```

Figure 2. K-means clustering algorithm from STAMP. ALTER suggests the OutOfOrder and $StaleReads$ annotations along the for loop, in combination with an additive reduction on the variable $delta$ (which is used to determine the termination of the overall algorithm). Parallelizing this algorithm using $StaleReads$ gives a speedup of 1.71x on 4 cores.

Has an outer while loop which checks for convergence and prevents these broken dependences from affecting the overall correctness. This alternate version of the algorithm has been shown in the literature to have the same convergence properties as the sequential version [30]. In fact, this algorithm belongs to a class of algorithms, commonly referred to as algebraic path problems [36], that can tolerate some stale reads. This class includes many popular algorithms such as the Bellman Ford shortest path algorithm, iterative monotonic data-flow analyses, Kleene’s algorithm (for deciding whether a regular language is accepted by a finite state automaton) and stencil computations.

Note that it is possible that embracing stale reads can increase the number of (outer loop) iterations needed to converge. For this benchmark, we observe that this increase is quite small in practice. This is expected as typically the size of $XVector$ is large (tens of thousands of elements) while an iteration will read a small number of stale values (at most $(N-1) \times \text{chunkFactor}$ values on an $N$-way multicores). Using ALTER, this parallelization gives a speedup of 1.70x with 4 cores for a problem size of 40,000.

The second example (see Figure 2) shows the main loop of the K-means clustering algorithm. ALTER suggests the loop can be parallelized with either OutOfOrder or $StaleReads$ in combination with an additive reduction on the variable $delta$. In this case, OutOfOrder and $StaleReads$ are equivalent with respect to the program’s execution, because every read of a shared variable (new_centers and new_centers_len) is followed by a write to the same location. Thus, even under the $StaleReads$ model there will not be any stale reads in the execution trace, because conflicts in the write sets would cause such concurrent iterations to conflict (this is clarified in the next section). Nonetheless, annotating the loop with $StaleReads$ can lead to higher performance than OutOfOrder, as it is not necessary to track or compare the read sets within ALTER.

Figure 3. ALTER annotation language

### 3. ALTER Annotation Language

ALTER provides an annotation language for specifying the parallelism in loops (see Figure 3). For all annotated loops, ALTER treats each iteration as a transaction that executes atomically and in isolation. The conditions under which an iteration commits its results are governed by the annotation \( A \), which contains two components: a parallelism policy \( P \) and, optionally, a set of reductions \( R \).

The parallelism policy can be one of two types:

1. **OutOfOrder** specifies that ALTER may reorder the loop iterations, so long as the execution is equivalent to some serial ordering of the iterations. This corresponds to the database notion of conflict serializability; two concurrent iterations can commit so long as the write set of one does not overlap the read set of the other. OutOfOrder preserves the semantics of the original program if the iterations are commutative.

2. **StaleReads** is more permissive than OutOfOrder: in addition to reordering iterations, the values read in a given iteration may be stale. All stale reads are drawn from a consistent but possibly obsolete snapshot of the global memory. The degree of staleness is bounded: the memory state seen by iteration \( i \), which writes to locations \( W \), is no older than the state committed by the last iteration to write to any location in \( W \). (The only exception is that of reduction variables, which do not count as part of \( W \).)

This model corresponds to the database notion of snapshot isolation: two concurrent iterations can commit so long as their write sets do not overlap. Snapshot isolation is a popular alternative to conflict serializability in the database community, as it leads to better performance. It is adopted by several major database management systems, including InterBase, Oracle, PostgreSQL and Microsoft SQL Server (2005 onward). However, to date there has been no programming language or runtime support for snapshot isolation as a mechanism for loop parallelization.

The second part of an ALTER annotation is an optional set of reductions. Each reduction is specified by the name of a program variable, as well as an operation that is commutative and associative. The annotation asserts that every access to the variable within the loop represents an update using the corresponding operation. For example, if the operation is \( + \), then the variable may appear only in statements of the form \( var += value \). Note that this also prohibits any reads of \( var \) elsewhere in the loop.

ALTER guarantees that upon completion of the loop, each reduction variable has the value corresponding to a serial execution of the operations that updated it. Note that under the OutOfOrder execution model, annotating reductions will not impact the final values assigned to reduction variables, as OutOfOrder guarantees that all variables (not just reduction variables) are updated in a manner that is consistent with a serial execution. However, annotating reductions can nonetheless improve the performance under OutOfOrder, as iterations that were previously serialized by a dependence on a reduction variable can now execute in parallel. In the case of StaleReads execution, annotating reduction variables can impact the final values of those variables (but not any other variables) as well as impacting performance.

In addition to the parameters specified in the annotation language, ALTER also allows the user to specify a chunk factor \( cf \), which dictates the granularity of the execution. While our description above deals in terms of individual iterations, in practice it is beneficial to group multiple iterations together for improving the efficiency of OutOfOrder and StaleReads execution. The semantics can be understood in terms of chunking: the original loop \( L \) is refactored into a nested loop \( L' \) in which each iteration of \( L' \) represents \( cf \) iterations of \( L \). The chunk factor can be designated on a per-loop basis, or globally for the entire program.

### 4. ALTER Compiler and Runtime

Given a sequential program and a loop to parallelize the ALTER compiler produces a concurrent program with embedded calls to the ALTER runtime library. The program is parameterized by some additional inputs which indicate the semantics to be enforced for each loop. If the user provides annotations for a loop, then these are used to generate the parameters. Otherwise, likely annotations can be inferred by testing their conformance to a test suite (see Section 5). Section 4.2 describes the parameters governing the execution and the assignments needed to exploit the parallelism allowed by the annotations. A salient feature of the ALTER framework is that the output of the compilation process is a deterministic parallel program. Details of how this is achieved are provided in Section 4.3.

#### 4.1 Program Transformation

Program transformations are implemented as phases in the Microsoft Phoenix compiler.

**Deterministic Fork Join Model**

The ALTER compiler transforms the program to use a process-based fork-join model of computation. The model provides efficient isolation between concurrently executing loop iterations through copy-on-write page protection. Figure 4 shows what the transformed program looks like. The shaded vertices and edges in the figure represent the original sequential control flow.

The high-level functionality of the transformation is to:

1. Create \( N \) processes that have identical stack and heap states (apart from ALTER’s internal variables), corresponding to the program state on entry to the loop. These \( N \) private memories are copy-on-write (COW) mappings of a committed memory state. Thus, just before the loop, there are \( N + 1 \) versions of memory. In the figure, \( \bullet \) and \( \bigcirc \) describe the implementation of this functionality using Win32 system calls.

2. Distribute iterations to processes and orchestrate a lock-step execution where processes repeatedly: \( \bigcirc \) pickup new iterations to execute, \( \bullet \) execute them concurrently in isolation on their own private memory while tracking read and write sets, \( \bigcirc \) validate and commit changes one after another to the committed memory state, \( \bigcirc \) re-synchronize their private memory with the committed memory state once all processes have committed. These steps are repeated until the loop execution is complete.

To keep things simple, Figure 4 depicts the program transformation without chunking. The actual transformation introduces an additional inner loop such that each process executes a consecutive chunk of iterations between joins.

**Memory Management**

In addition to the above transformation, all calls to memory allocator methods are replaced with calls to the ALTERallocator. This transformation is essential to ensure that in a multi-process setting,
objects can be directly copied between processes without overwriting live values. The ALTERallocator is designed to be safe and efficient under a multi-process execution environment. It ensures safety by guaranteeing that no two concurrent processes are allocated the same virtual address. We do not describe the design in detail here except to say that it uses techniques similar to ones used by HOARD [3]. While HOARD is optimized to be efficient in a multi-threaded environment, the ALTERallocator is designed to be efficient in a multi-process environment. For example, the allocator is optimized to minimally use inter-process semaphores and mutual exclusion primitives. Such inter-process communication primitives are typically much more expensive than locking primitives that can be used in a multi-threaded setting.

**ALTER Collection Classes**

While simple induction variables can be identified via static analysis, induction variables of loops that iterate over elements of a heap data structure will not be detected by most compilers. To enable parallelization of such loops ALTER exposes a library of standard data structures that are commonly iterated over. When a user wants to parallelize such a loop, she could replace the data-structure with an equivalent ALTER collection class. ALTER internally manages the state associated with collection classes in a process-safe manner (details omitted for lack of space). Note that ALTER collections can also safely be used in a sequential program.

**4.2 Runtime Parameters**

As mentioned previously the ALTER compiler translates the sequential program into a concurrent program with some additional configuration parameters. Four different parameters are exposed, combinations of which can be used to enforce various formal guarantees for the loop.

1. The **ConflictPolicy** configuration parameter selects one among four different definitions of conflict, which are applied to all memory locations not corresponding to reduction variables. These four policies, **FULL**, **RAW**, **RAW** and **NONE** form a partial order with respect to the conditions under which they allow processes to commit. These terms have the natural intuitive meaning. **FULL** allows a process to commit only if neither its read or write set overlaps with the write set of all of the concurrent processes that were joined before it. **RAW** allows a process to commit only if its write set does not overlap with the write set of any of the concurrent processes joined before it. **RAW** allows a process to commit only if it has read set does not overlap with the write set of any of the concurrent processes joined before it. **NONE** does not check for any conflicts and allows all processes to commit.

2. The **CommitOrderPolicy** defines whether the iterations of the loop should commit in program order (**InOrder**) or are allowed to commit **OutOfOrder**.
3. ReductionPolicy takes a set of \( \langle \text{var}, \text{op} \rangle \) pairs and applies reduction as follows. Let \( S_t(x) \) denote the latest value of \( x \) in the committed memory. Let \( \text{old}S_t(x) \) and \( \text{new}S_t(x) \) denote the values of \( x \) in the private memory of transaction \( t \), at the start and end of its execution. ALTER modifies the state depending on the operation in consideration as follows. (1) if \( \text{op} \) is idempotent, that is \( \text{op} \in \{ \vee, \wedge, \max, \min \} \), then the committed memory state is updated as \( S_t(x) := S_t(x) \oplus \text{new}S_t(x) \). (2) if \( \text{op} = \text{+} \) then the committed state is updated as \( S_t(x) := S_t(x) + \text{new}S_t(x) - \text{old}S_t(x) \). \( x \) is handled similarly. Our framework currently only supports these 6 operations. The library also has partial support for programmer-defined reduction operations but this is not fully tested and is not exposed as yet.

4. Finally, ChunkFactor takes a integer that defines the chunk factor to be used. We omit this parameter in discussions below and refer to it only when relevant.

Parameters Respecting ALTER Annotations

The following theorems assert that the ALTER annotations, which represent constraints on the parallelism in loops, can be enforced via certain selections of the runtime parameters.

**Theorem 4.1.** Executing a loop under ALTER with:

- ConflictPolicy = RW
- CommitOrderPolicy = OutOfOrder
- ReductionPolicy = R

respects the annotation (OutOfOrder, R).

**Proof Sketch** The OutOfOrder annotation specifies that loop iterations are treated as transactions that commit subject to conflict serializability. ALTER provides isolation for iterations by executing each in its own address space. The RW conflict policy guarantees that two concurrent transactions will not both commit if the read set of one overlaps the write set of another, which is the criterion required for conflict serializability. Reordering of iterations is enabled by the OutOfOrder ordering policy.

**Theorem 4.2.** Executing a loop under ALTER with:

- ConflictPolicy = RAW
- CommitOrderPolicy = OutOfOrder
- ReductionPolicy = R

respects the annotation (StaleReads, R).

**Proof Sketch** The StaleReads annotation specifies that loop iterations are treated as transactions that commit subject to snapshot isolation. ALTER provides isolation by executing each iteration in its own address space. The RAW conflict policy guarantees that two concurrent transactions will not both commit if their write sets overlap, which is the criterion required for snapshot isolation.

Parameters Respecting Other Semantics

While our focus in this paper is to explore loop semantics that depart from ordinary execution models, ALTER can also be used to implement well-known models such as safe speculative parallelism and DOALL parallelism. This is asserted by the following theorems:

**Theorem 4.3.** Executing a loop under ALTER with:

- ConflictPolicy = RAW
- CommitOrderPolicy = InOrder
- ReductionPolicy = NONE

offers safe speculative parallelism (equivalent to sequential semantics).

**Proof Sketch** The iterations commit InOrder while respecting all RAW dependences, which implies that none of the dependences in the original program are broken.

**Theorem 4.4.** Executing a loop under ALTER with:

- ConflictPolicy = *
- CommitOrderPolicy = *
- ReductionPolicy = R

offers DOALL parallelism with a reduction \( R \).

**Proof Sketch** As DOALL parallelism applies when there are no dependences between iterations, the ConflictPolicy and CommitOrderPolicy are not relevant. Nonetheless, reductions can be supported using the ALTER framework.

While other combinations of the ALTER parameters also lead to sensible execution models, we did not find an analogue for them in practice or application for them in example programs. We leave potential investigation of these models for future work.

### 4.3 Determinism

A salient feature of ALTER is that given a deterministic sequential program as input ALTER produces a deterministic parallel program. That is, every time the generated executable is run with the same program input and the same values for number of processes \( N \), the chunk factor \( cf \) and configuration parameters (ConflictPolicy, CommitOrderPolicy, ReductionPolicy) it produces the same output so long as the program terminates. If the program crashes or does not terminate this also happens deterministically. The runtime avoids any kind of races by enforcing runtime barriers.

Determinism follows from the following facts: (1) all concurrent processes have independent memory spaces, (2) no process is allowed to execute \( \text{join}() \) until all processes have completed their work, (3) processes commit their changes sequentially to the committed memory state, (4) updates from the committed memory state to private memory spaces occur only after all processes have committed, and (5) the same conflicts are detected for every execution with the same inputs. Determinism is a desirable property for a framework like ALTER that uses test suite conformance as the validation criterion, because the correctness of each test can be determined in a single execution.

### 5. Annotation Inference

In addition to implementing parallelism consistent with the programmer’s annotations, ALTER can also be used to infer a set of annotations that are likely valid for a given loop. Because this inference algorithm is unsound, it is important to use it carefully. We discuss specific application scenarios in the next section.

The annotation inference works via a simple test-driven framework. Given a program, ALTER creates many different versions, each containing a single annotation on a single loop. Together, these versions exhaustively enumerate the ways in which one could add a single annotation to the program (details below). Then, ALTER runs each of these programs on every input in the test suite. Because the ALTER runtime is deterministic, only one execution of each test is needed. Those versions matching the output of the unmodified sequential version (according to a program-specific correctness criterion) are presented to the user as annotations that, in isolation, are likely valid. If the user would like to further test the validity of multiple annotations in combination, she can submit a partially-annotated program to ALTER, which will cause it to test those annotations and search for ways in which to extend them.

To enumerate the candidate annotations, our current implementation works as follows. ALTER systematically explores values for

$P$ and $R$ (see Figure 3) by fixing the chunk factor at 16 and evaluating all valid candidates for the other runtime parameters. For each reduction $R$, a bounded search over reduction variables and operators is performed. The search is restricted to (i) apply one of six reduction operators ($+\times\max\min\land\lor$), and (ii) apply the same reduction operator (or lack thereof) to all stack variables\(^1\). Also a search for a valid reduction is performed only if none of the annotations of the form $(P,e)$ are valid.

After ascertaining valid annotations, an iterative doubling algorithm is used to find an appropriate chunk factor. Starting from a candidate value of 1 the chunk factor is iteratively doubled until a performance degradation is seen over two successive increments. The candidate that led to the best performance is then chosen as the chunk factor. Our results indicate that the chunk factor is dependent only on the loop structure and not on the inputs. Figure 5 shows how performance varies with increasing chunk factors for different inputs of $K$-means. As can be seen the best performing chunk factor for all 4 inputs remains the same. Similar behavior is observed for other benchmarks.

In addition to reporting the set of annotations that lead to valid executions, ALTER also gives hints as to the cause of failure for annotations that are unsuccessful. For each annotation, the reported outcome is one of the following: $success, failure \in \{\text{crash, timeout, high contention, output mismatch}\}$. $Success$ represents the case where the execution produces a valid output. Failure cases can be classified into cases where no output is produced ($\text{crash, timeout}$) and cases where an output is produced but it is either incorrect ($\text{output mismatch}$) or is unlikely to lead to performance improvements ($\text{high contention}$). A $timeout$ is flagged if the execution takes more than 10 times the sequential execution time. An execution is flagged as having high contention if more than 50% of the attempted commits fail. Both of these behaviors are correlated with performance degradation and hence we deem them as failures.

\(^1\)This is sufficient for our current benchmarks. It should be fairly straightforward to extend the search strategy to explore different reductions for different variables. Because reduction variables are not allowed to interact, either with each other or with the program variables, each variable can be tested independently without leading to a combinatorial explosion.

6. Usage Scenarios

To explore concrete applications of ALTER in real-world contexts, we consider three scenarios – manual parallelization, assisted parallelization, and automatic parallelization. While our primary target is assisted parallelization, under certain circumstances ALTER can also make sense for purely manual or automatic parallelization. We summarize these scenarios in Figure 1 and expand on them below.

**Assisted parallelization** In this scenario, a user is attempting to parallelize a code base for which she has partial but incomplete knowledge. For example, perhaps the user has authored part of the system, but relies on third-party libraries as well. In such a situation, ALTER serves a natural role in assisting the user to parallelize the code. By evaluating various loop annotations via executions on test suites, ALTER can suggest which models of parallelism are likely to be valid and beneficial for each loop in the program. The user can investigate these suggestions to determine whether or not they are sound before integrating them into source base. In addition, ALTER’s suggestions could serve as a useful upper bound for certain kinds of parallelism in the program. If ALTER does not find likely parallelism in any loop, then perhaps a new algorithm will be needed to leverage multicore hardware.

**Manual parallelization** This scenario applies to cases in which the user of ALTER is authoring a new parallel program or is already equipped with a deep understanding of an existing code base. In this case, the user can think of ALTER as providing an API for exploiting known parallelism in the program. All of the annotations are written by the user herself. The ALTER runtime system could be shipped as part of a product, or applied only for internal prototyping in order to quickly explore the speedups offered by various transformations. In the latter case, the most beneficial transformations may be re-written manually (without the ALTER runtime system) to further customize and optimize the performance.

**Automatic parallelization** In the final scenario (which remains largely hypothetical), ALTER is applied as an autonomous parallelization engine. Perhaps this could make sense for obscure legacy codes, in which it is unduly expensive for new developers to fully understand the intricacies of the implementation. ALTER could be used to infer parallel annotations by evaluating them for correctness across a large and rigorous test suite. In the case of legacy codes, test suites often provide the only arbiter as to whether changes in the environment have violated implicit assumptions of the code. Just as many human intuitions about very complex systems can only be verified via testing, there might be cases where it is not unreasonable to utilize testing as the sole correctness criterion for a compiler-directed transformation.

Nonetheless, to make sense in a production environment, additional flexibility is likely needed to embrace ALTER as an automatic parallelization engine. For example, if parallel speedups are urgently needed to proceed with whole-system prototyping (e.g., to evaluate the user experience of a new gaming engine), then perhaps ALTER could be applied temporarily until a human developer has a chance to step in and laboriously verify the changes. Alternately, there may be end-user applications where speed is more important than correctness. For example, one may desire a low-latency preview of multimedia content before the official decoder has finished rendering it, even if the preview has a chance of being wrong. Or,
on a mobile platform, if the battery is low one may want to quickly execute some application (with some chance of failure) rather than initiating a slower execution that is guaranteed to timeout due to a dead battery.

7. Experimental Evaluation

We evaluate ALTER with algorithms from Berkeley’s dwarfs [26] and sequential versions of the STAMP [8] benchmarks (see Table 2). A dwarf represents an algorithmic method that captures a commonly used pattern of computation. We utilize all dwarfs for which we could find a good representative algorithm and all STAMP benchmarks that we could get to compile on Windows2.

Table 2 describes the benchmarks used. Our transformations target a single loop in each benchmark. For many benchmarks the main computation happens in a single loop nest; we report results for the outermost loop that is amenable to parallelism. For benchmarks containing multiple important loops, the targeted loop is indicated in the description column of the table. For each benchmark, we use test inputs to infer the annotations and then use a larger input (shown in bold) to measure performance. All performance measurements are conducted on an 8-core Intel Xeon machine (2 × quad core at 2.4GHz) with a 64-bit Windows Server 2008 operating system.

7.1 Results of Annotation Inference

We utilized the annotation inference algorithm to infer all annotations used in our evaluation. Correctness of the program output was evaluated on a case-by-case basis. For 4 of the benchmarks (Labyrinth, Genome, GSdense, GSsparse) assertions in the code validate the output. For the remaining programs, we utilized a program-specific output validation script which often made approximate comparisons between floating-point values.

The results from the inference algorithm are reported in Figure 6. In addition to the models exposed by our language we also check if the program can be parallelized by some existing auto-parallelization techniques. We add a check in join() to see if the loop has any loop-carried dependences. The results of this check are shown in column dep. We also check to see if the loop is amenable to thread level speculation (TLS). The outcome of this check could be one among (success, failure ∈ (crash, timeout, high contentation)). Interestingly, we find that in all cases a single test is sufficient to identify incorrect annotations. We find that when TLS, OutOfOrder or StaleReads fail, they fail either due to timeouts or due to a large number of conflicts. The only exception is AggloClust, where the application crashes under OutOfOrder and TLS. In these two cases the machine runs out of memory (due to very large read sets). We find that an incorrect reduction leads either to an invalid output or a timeout. An interesting case is the + reduction for SG3D. The convergence check in this algorithm looks for \( \max v_i(\text{error}_i) < \text{threshold} \) so a max reduction works. A + leads to a check of the form \( \sum v_i(\text{error}_i) < \text{threshold} \) which also produces a valid output but convergence takes much longer. Other reductions lead to a deviation of ±0.01% from sequential output in some entries.

Overall we find that all but one benchmark (Labyrinth) can be parallelized with ALTER. Both SSCA2 and Genome which are known to be amenable to OutOfOrder [8] also lead to a correct execution under StaleReads. This is because all variables that are read in the loop are also written to. Hence it is sufficient to check for WAW conflicts alone and no read instrumentation is required. Though it is known that K-means can be parallelized with

Figure 6. Results of annotation inference. The table shows whether there is a dependence carried by the loop (Dep) as well as the results for thread-level speculation (TLS), OutOfOrder execution (OO), and StaleReads (Stale). High conflict results are abbreviated as h.c. Reduction operators are shown where needed.

OutOfOrder we find that it leads to a very slow execution. We find that the only practical execution model for K-means is to use a combination of StaleReads and + reduction.

Four other benchmarks (GSdense, GSsparse, Floyd, and SG3D) are tolerant to stale reads and can also be parallelized either with StaleReads or a combination of StaleReads and reduction. We find that only three benchmarks have no loop carried dependences and (of those with dependences) only one is amenable to efficient speculation.

7.2 Performance Results

The results for all annotations that lead to a valid execution during testing are shown in Figures 7 through 12. A speedup of up to 4.5X is observed (ignoring “trivial” benchmarks with no loop carried dependences) with 8 cores. For the two benchmarks (Genome and SSCA2) that are amenable to multiple annotations, we find that StaleReads leads to much better performance than OutOfOrder. This is because enforcing StaleReads does not need read instrumentation. We report the size of the read and write sets per transaction as well as retry rates in Figure 13. As can be seen by comparing the amount of instrumentation for OutOfOrder and StaleReads for a given benchmark, there is a much larger number of reads (instrumented by OutOfOrder) than writes (instrumented by both OutOfOrder and StaleReads) within a transaction3. Further, we find that for Genome TLS performs nearly as well as OutOfOrder but not as well as StaleReads.

Benchmarks GSdense, GSsparse, and Floyd when executed under StaleReads lead to no conflicts. This is because while these loops have many RAW dependences there are no loop-carried RAW dependences. We also find that breaking RAW dependences hardly increases the number of iterations needed to converge (GSdense increases from 16 to 17, while GSsparse increases from 20 to 21). Unfortunately, both GSdense and GSsparse are memory bound and hence do not scale well beyond 4 cores. Like the above benchmarks SG3D leads to no conflicts under StaleReads with reduction. Among max and + reduction we find that using + degrades performance as it leads to a significant increase in the number of iterations to converge (1670 to 2752).

We find that the speedup obtained for K-means depends on the number of clusters to be formed. The larger the number of

Because this analysis is automatic and does not depend on any special knowledge of the program, the overheads observed are likely to generalize to other programs.
clusters to be formed, the fewer the conflicts. As can be seen from Figure 12, when the number of clusters decreases from 1024 to 512 the speedup comes down from 2.8X to 1.7X. So long as the probability that two points map to the same cluster is low, the algorithm should see a speedup. Further note that while the speedup varies, the best parallelism policy or chunk factor does not change with input. As seen before, both inference and evaluation inputs perform best at the same chunk factor.

### 7.3 Comparison with Manual Parallelization

Finally, we manually parallelize two of the benchmarks in order to provide a realistic parallel baseline for ALTER. We manually implement a multi-threaded version of Gauss-Seidel that mimics the runtime behavior of StaleReads by maintaining multiple copies of XVector that are synchronized in exactly the same way as a chunked execution under ALTER. We also parallelize K-means using threads and fine-grained locking.

As shown in Figure 10, ALTER performs comparably to manual parallelization on Gauss-Seidel. However, on K-means, it performs 20-47% slower than manual parallelization (considering all tests between 4 and 8 cores) as shown in Figure 12. This slowdown is due to the overhead of the ALTER runtime system as it explores parallelism via optimistic, coarse-grained execution rather than pessimistic fine-grained locking.

### 8. Related Work

**Parallelizing compilers** Compilers rely on static analysis to identify parts of the program that can be parallelized. Often they target simple forms of loop parallelism like DoAll and pipeline parallel loops or loops with simple reductions [16]. Parallelizing compilers are typically restricted by the accuracy of static analyses such as data dependence analysis and alias analysis [18]. Richer forms of parallelism can be identified via commutativity analysis [2, 14] that detects if two program tasks commute with each other or not. The analysis needs to be able to prove the equivalence of the final memory state with either order of execution of the tasks before applying a parallelizing transformation. One of the contributions of ALTER is to provide a test-driven framework to identify whether iterations of a loop are likely to commute with each other.

Another interesting class of compiler time transformations exploit pipeline parallelism [29] by partitioning the program dependence graph across multiple processors. While we do not consider

pipeline parallelism in this paper, it could be interesting to extend ALTER to this context in the future.

**Profile driven parallelization** Profile driven parallelization tools augment compiler driven transformations by using profile inputs to identify DoAll and pipeline parallelism in programs [28, 37, 39]. Speculative parallelization [10, 13, 27, 32, 40] is another popular form of parallelization enabled by profile driven tools. Execution of speculatively parallelized programs typically requires support for thread level speculation either in hardware [19, 35] or in software [10, 13, 27, 38]. To the best of our knowledge all existing profile driven tools that exploit inter-iteration parallelism in loops are restricted to exploring forms of parallelism that guarantee sequential semantics for the loop. ALTER exposes and exploits alternative semantics, resulting from breaking selected dependences, that nonetheless preserve overall functionality.

**Transactional memory systems** Software transactions have been proposed as an alternative to traditional lock based programming. A transactional memory system [17, 23] is needed to support concurrent execution of software transactions. Transactional memory systems try to provide conflict serializability as the correctness criterion, however the exact semantics provided by most STMs is captured better by a correctness guarantee referred to as opacity [15]. ALTER is a test-driven framework that helps identify whether the iterations of the loop can be encompassed within software transactions. In addition it provides a unified deterministic runtime that can support additional parallel models. In addition to conflict serializability ALTER can identify loops which lead to correct behavior under two alternative execution models.

**Language constructs for expressing parallelism** Plenty of programming language research has gone into developing new constructs for expressing parallelism. Most of these introduce richer semantics that cannot be detected by existing parallelization tools. The Galois programming system introduces constructs to iterate over sets (optimistic iterators) and allows programmers to specify conditions under which methods commute [21, 22]. With these constructs a programmer can write loops whose iterations can execute optimistically in parallel and commit out of order as long as there are no commutativity violations. The revisions program-
behavior oriented parallelization framework [13] that uses process based isolation for speculative parallelization, and (2) the Grace runtime system [4] that forks off threads as processes in an attempt to avoid common atomicity related concurrency errors.

9. Conclusions
Despite decades of research on automatic parallelization, the results achievable by a compiler are rarely comparable to that of a human. We believe that one of the primary limitations holding compilers back is their conservative treatment of memory dependences. Though humans can and do re-arrange dependences – which are often artifacts of the implementation, or non-essential elements of the algorithm – compilers, for the most part, do not.

In this paper, we take a first step towards bridging this gap by proposing ALTER: a system that violates certain memory dependences in order to expose and exploit parallelism in loops. We emphasize that ALTER is not intended to completely replace a human; as its inferences are unreadable, we still rely on human judgement to drive the parallelization process. However, ALTER could greatly assist the developer by providing a new set of parallelism primitives as well as suggestions regarding their most effective use.

Our evaluation indicates that the parallelism exploited by ALTER is beyond the reach of existing static and dynamic tools. In particular, for one third of our benchmarks, the use of snapshot isolation – allowing stale reads within loops – enables parallel execution even when prior techniques such as speculative parallelism and out-of-order commit do not.
