Setting 2 variables at a time yields a new lower bound for random 3-SAT

Dimitris Achlioptas†

December 16, 1999

Abstract
Let $X$ be a set of $n$ Boolean variables and denote by $C(X)$ be the set of all 3-clauses over $X$, i.e. the set of all $8\binom{n}{3}$ possible disjunctions of three distinct, non-complementary literals of variables in $X$. Let $F(n, m)$ be a random 3-SAT formula formed by selecting, with replacement, $m$ clauses uniformly at random from $C(X)$ and taking their conjunction. Finally, let us say that a sequence of events $E_n$ occurs with high probability (w.h.p.) if $\lim_{n \to \infty} \Pr[E_n] = 1$. The satisfiability threshold conjecture asserts that there exists a constant $r_3$ such that $F(n, r_n n)$ is w.h.p. satisfiable for $r < r_3$ and w.h.p. unsatisfiable for $r > r_3$. Experimental evidence suggests $r_3 \approx 4.2$.

We prove $r_3 > 3.145$ improving over the previous best lower bound $r_3 > 3.003$ due to Frieze and Suen. For this, we introduce a new satisfiability heuristic and analyze its performance. The framework we develop for the analysis of our heuristic allows us to recover most of the previous lower bounds along with our new bound in a uniform manner and with little additional effort.

1 Introduction
The question which originally motivated the study of random(ly chosen) satisfiability (instances) can be put roughly as “Are typical instances of satisfiability hard?” While “hard” here is vis-à-vis the problem’s NP-completeness, quantifying “typical” is a difficult problem in itself. Considering random formulas allows one to sidestep this thorny issue.

Some early results on the performance of the Davis-Putnam (DP) algorithm [10, 9] on random formulas, the one most often quoted being due to Goldberg [20], suggested that SAT is easy on average. Franco and Paull [16], though, pointed out that the distribution of instances used in [20] is so greatly dominated by easily satisfiable instances that, if one tries truth assignments completely at random, the expected number of trials until finding a satisfying one is $O(1)$. Moreover, they considered the performance of the DP algorithm on random instances of $k$-SAT. More precisely, let $F_k(n, m)$ denote a random formula in Conjunctive Normal Form (CNF) with $m$ clauses over $n$ Boolean variables, where the clauses are chosen uniformly, independently and with replacement among all $2^k\binom{n}{k}$ non-trivial clauses of length $k$, i.e. among $k$-clauses with distinct non-complementary literals. Franco and Paull [16] showed that for all $k \geq 3$ and every constant $r > 0$, with probability $1 - o(1)$, the DP algorithm takes an exponential number of steps to report the satisfying truth assignments of $F_k(n, r n)$, i.e. either to report all (“cylinders” of) solutions, or that no solutions exist.

In a seminal paper, extending the ground-breaking result of Haken [21] on the worst-case complexity of resolution, Chvátal and Szemerédi [5] used $F_k(n, rn)$ to provide examples of formulas that are hard to prove unsatisfiable for any resolution-type strategy (such as the DP algorithm). In particular, they showed that for all $k \geq 3$, if $r 2^{-k} > 0.7$ then there exists $\epsilon = \epsilon(k, r) > 0$ such that with probability $1 - o(1)$, $F_k(n, rn)$ is unsatisfiable but every resolution proof of its unsatisfiability must generate at least $(1 + \epsilon)n$ clauses.

In [35], Selman, Mitchell and Levesque gave extensive experimental evidence suggesting that for $k \geq 3$ there is a range of the clauses-to-variables ratio, $r$, within which it seems hard even to decide if a randomly chosen $k$-SAT instance is satisfiable or not (as opposed to finding all satisfying truth assignments or giving a proof of unsatisfiability). For example, for $k = 3$ their experiments draw the following remarkable picture. For $r < 4$, a satisfying truth assignment can be easily found for almost all formulas; for $r > 4.5$, almost all formulas are unsatisfiable; for $r \approx 4.2$, a satisfying truth assignment can be found for roughly half the formulas and around this point the computational effort to find a satisfying truth assignment, whenever one exists, is maximized. Let

$$S_k(n, r) = \Pr[F_k(n, rn) \text{ is satisfiable}].$$

In [6], the following possibility was put forward and has since become a folklore conjecture.

**Satisfiability Threshold Conjecture** For each $k \geq 2$, there exists a constant $r_k$ such that for any $\epsilon > 0$,

$$\lim_{n \to \infty} S_k(n, r_k - \epsilon) = 1, \quad \text{and} \quad \lim_{n \to \infty} S_k(n, r_k + \epsilon) = 0.$$

This conjecture, which motivates our work, has attracted a lot of attention in computer science, mathematics and, more recently, in mathematical physics [29, 30, 32, 31]. We introduce a new algorithmic approach to this problem and use it to prove

**Theorem 1** For all $r \leq 3.145$, $F_3(n, rn)$ is satisfiable with probability $1 - o(1)$.

For the connections of random formulas to proof-complexity and computational-hardness we refer the interested reader to the excellent surveys by Beame and Pitassi [1] and Cook and Mitchell [8], respectively. The rest of the paper is organized as follows. In Section 2 we summarize most known results regarding the conjecture. In Section 3 we give a more detailed account of our contribution and its relationship to past work. In Section 4 we give the preliminaries for the analysis and present the main tools that we use. Finally, in Section 5 we prove our main result.

## 2 Known results for random $k$-SAT

We will say that a sequence of events $E_n$ occurs with high probability (w.h.p.) if $\lim_{n \to \infty} \Pr[E_n] = 1$. If $\liminf_{n \to \infty} \Pr[E_n] > 0$ we will say that $E_n$ holds with positive probability. Finally, throughout the paper we will omit floors and ceilings when this does not cause confusion.

### 2.1 Random 2-SAT

For $k = 2$, Chvátal and Reed [6], Goerdt [19] and Fernandez de la Vega [14] independently proved the conjecture, in fact determining $r_2 = 1$. It is important to note that 2-SAT being solvable in polynomial time [7] means that we have a simple characterization of unsatisfiable 2-SAT formulas. Indeed, both [6] and [19] make full use of this characterization as they proceed by focusing on the
emergence of the “most likely” unsatisfiable subformulas in $F_2(n, rn)$. Also using this characterization, Bollobás et al. [2] recently completely determined the “scaling window” for random 2-SAT, showing that the transition from satisfiability to unsatisfiability occurs for $m = n + \lambda n^{2/3}$ as $\lambda$ goes from $-\infty$ to $+\infty$. A useful lemma that follows immediately from their results is the following (with a bit of work Lemma 1 also follows from [19]).

**Lemma 1** Let $F$ be a random formula formed by taking the conjunction of $F_2(n, rn)$ and $F_1(n, q)$ (over the same $n$ variables). If $q = \text{polylog}(n)$, then for any constant $r < 1$, $F$ is satisfiable w.h.p.

### 2.2 Random 3-SAT

For $k \geq 3$, much less progress has been made. Neither the value, nor even the existence of $r_k$ has been established. A big step towards the latter was made by Friedgut [17].

**Theorem 2 ([17])** For every $k \geq 2$, there exists a sequence $r_k(n)$ such that for any $\epsilon > 0$,

$$
\lim_{n \to \infty} S_k(n, r_k(n) - \epsilon) = 1, \quad \text{and} \quad \lim_{n \to \infty} S_k(n, r_k(n) + \epsilon) = 0 .
$$

The following immediate corollary of Theorem 2 is very useful, as it allows one to establish $r_k \geq r^\ast$ only by showing that $F_k(n, r^\ast n)$ is satisfiable with positive probability.

**Corollary 1** If for a given $r$, $\lim_{n \to \infty} S_k(n, r) > 0$ then for any $\epsilon > 0$, $\lim_{n \to \infty} S_k(n, r - \epsilon) = 1.$

The first upper bound for $r_3$ was given by Franco and Paull [16] who observed that the expected number of satisfying truth assignments of $F_3(n, rn)$, $(2(7/8)^n)^n$, is $o(1)$ when $r > r^\ast = 5.191...$. Since then, and especially in recent years, there has been steady progress in terms of improving this bound. In [3], Broder, Frieze and Upfal were the first to point out that this bound is not tight and showed $r_3 < r^\ast - 10^{-7}$. Indeed, shortly afterwards, El-Maftouhi and Fernandez de la Vega [13] proved $r_3 < 5.08$ and, independently, Kamath et al. [23] proved $r_3 < 4.758$. Later, Kioumous et al. [25] improved the bound even further to $r_3 < 4.601$, by using a much more direct and simple approach than [13, 23]. Independently, Dubois and Boufkhad [11], using a method similar to [25], obtained $r_3 < 4.64$. By improving upon an estimate in [25], Janson, Stamatou and Vanvakari [22] showed $r_3 < 4.596$. Very recently, Dubois, Boufkhad and Mandler [12] proved $r_3 < 4.506$.

Unlike upper bounds, that come from probabilistic counting arguments, all lower bounds for $r_3$ are algorithmic. Also unlike upper bounds, there has been no progress in terms of bounding $r_3$ from below since 1994. The first analysis of an algorithm on $F_3(n, rn)$ was given by Chao and Franco [4] who showed that the UNIT CLAUSE (UC) algorithm has positive probability of finding a satisfying truth assignment for $r < 8/3 = 2.66...$ and, when combined with a “majority” rule, for $r < 2.9$. Since, though, these algorithms succeed only with positive probability this did not imply $r_3 \geq 2.9$.

The first lower bound for $r_3$ comes from a result of Franco [15], who considered the pure literal heuristic on $F_3(n, rn)$. This heuristic satisfies a literal iff its complement does not appear in the formula, thus only making “safe” steps. Franco showed that for $r < 1$, w.h.p. the pure literal heuristic eventually sets all the variables, implying $r_3 \geq 1$ (although the notion of $r_k$ did not exist at the time). After $r_2 = 1$ was established, making $r_3 \geq 1$ trivial, the next lower bound, $r_3 \geq 1.63$, was given by Broder, Frieze and Upfal [3] who proved that the pure literal heuristic w.h.p. sets all the variables for $r \leq 1.63$ (they, also, proved that it fails for $r > 1.7$). The last lower bound for $r_3$ was given by Frieze and Suen [18]. They considered two generalizations of UC, called SC and GUC respectively, and determined their exact probability of success on $F_3(n, rn)$. In particular, they showed that for $r < 3.003...$, both heuristics succeed with positive probability. Moreover, they proved that a modified version of GUC, which performs a very limited form of backtracking, succeeds w.h.p. for such $r$, thus yielding the best known lower bound for $r_3$ prior to this work.
3 A new approach

In this paper we improve the lower bound for random 3-SAT to \( r_3 > 3.145 \). For this, we introduce a new satisfiability heuristic and a framework to analyze its performance. The main novelty of our heuristic is that, unlike all algorithms analyzed thus far, it often sets two variables “at a time”. In particular, with the exception of the pure literal heuristic, all the algorithms discussed in the previous section proceed in rounds of the following type: at the beginning of each round precisely one literal \( \ell \) is set to 1; the clauses containing \( \ell \) are removed; each \( i \)-clause \( c \) containing \( \bar{\ell} \) “shrinks” and becomes an \((i-1)\)-clause; literals corresponding to unit-clauses always have highest priority (unit-clause propagation); failure occurs iff a 0-clause is ever generated. Schematically, we can describe all these algorithms as follows:

\[
\text{While there exist unset variables}
\begin{align*}
  &\text{If there exist unit-clauses} \\
  &\text{then pick a unit-clause } \ell \text{ uniformly at random and satisfy it} \\
  &\text{else select a literal } \ell \text{ and satisfy it}
\end{align*}
\]

Let us write u.a.r. for uniformly at random. The different algorithms implement select as follows:

- **uc**: Pick \( \ell \) u.a.r. among all literals corresponding to unset variables.
- **uc with majority**: Pick an unset variable \( v \) u.a.r. Pick the literal \( \ell \in \{v, \bar{v}\} \) which appears in the fewest remaining 3-clauses (break ties u.a.r.).
- **sc**: If no 2-clauses remain, pick \( \ell \) u.a.r. among all literals corresponding to unset variables. Else, pick a remaining 2-clause \( c = (\ell_1 \lor \ell_2) \) u.a.r. and pick \( \ell \in \{\ell_1, \ell_2\} \) u.a.r.
- **guc**: Among all remaining clauses of shortest length, pick u.a.r. a clause \( c = (\ell_1 \lor \cdots \lor \ell_j) \). Pick \( \ell \in \{\ell_1, \ldots, \ell_j\} \) u.a.r.

In this schema our heuristic, called **TT** for “Two at a Time”, becomes

\[
\text{While there exist unset variables}
\begin{align*}
  &\text{If there exist unit-clauses} \\
  &\text{then pick a unit-clause } \ell \text{ u.a.r. and satisfy it} \\
  &\text{else If there exists a 2-clause } c = (\ell_1 \lor \ell_2) \\
  &\text{then gently-satisfy}(\ell_1, \ell_2) \\
  &\text{else pick u.a.r. an unset variable and assign it 0/1 u.a.r.}
\end{align*}
\]

**gently-satisfy**(\( \ell_1, \ell_2 \)): Let \( v_1 \neq v_2 \) be the two variables underlying \( \ell_1, \ell_2 \). Among all three assignments to \( v_1, v_2 \) satisfying \( c = (\ell_1 \lor \ell_2) \), pick the one which causes the fewest number of 3-clauses to become 2-clauses.

The framework that we develop for the analysis of our heuristic allows us to recover the new bound and the bounds corresponding to uc, uc with majority, and sc, guc in a uniform and rather simple manner (note that by Corollary 1, the results in [4] for uc and uc with majority immediately give lower bounds for \( r_3 \), weaker though than the bound from [18]). This uniformity and simplicity is the result of employing a number of powerful tools developed by others. For example, Corollary 1 lets us boost our positive probability of finding a satisfying truth assignment to a high \((1 - o(1))\) probability of satisfiability. This allows us to avoid the backtracking necessary
in [18]. Also, Lemma 1 allows us to run the algorithms not until all variables are set but until the remaining clauses form an “easy-to-satisfy” formula. This way we avoid dealing with the, rather messy, last phases of the algorithms’ execution. The central tool of our analysis is a powerful theorem of Wormald [36] which will let us approximate the number of remaining 2- and 3-clauses at the end of each round. The applicability of this theorem, in turn, is based on a lazy-server lemma that we prove which is of independent interest.

In this extended abstract we only show how to recover our main result \( r_3 > 3.145 \). The derivation of the other bounds follows along similar, if simpler, lines.

4 Preliminaries

There are several natural ways to implement \( \texttt{tt} \) into a specific procedure to be analyzed. Unfortunately, most of them lead to some subtle but nasty technical complications (which we will not discuss here). The most easily analyzed implementation is described below. At first glance, it may appear to differ significantly from \( \texttt{tt} \), but in fact the differences are superficial and are only aimed at simplifying the analysis.

The algorithm runs for rounds \( t = 0, 1, \ldots \) and precisely two variables are assigned a permanent value in each round. After \( t \) rounds, \( C_i(t) \) denotes the set of remaining \( i \)-clauses, \( V(t) \) the set of unset variables, and \( L(t) \) the set of literals corresponding to unset variables. Denote \( C_i(t) = \left| C_i(t) \right| \).

Note that \( |L(t)| = 2|V(t)| = 2(n - 2t) \). For a literal \( \ell \), let \( v(\ell) \) denote its underlying variable. For technical reasons, it will be useful to occasionally perform just-satisfy instead of gently-satisfy.

\[ \text{just-satisfy}(\ell_1, \ell_2): \text{Pick u.a.r one of the three value assignments satisfying } (\ell_1 \lor \ell_2) \text{ and assign it to } v(\ell_1), v(\ell_2). \]

The random variables \( W(0), W(1), \ldots \) and \( E(0), E(1), \ldots \) appearing in the description of \( \texttt{mtt} \) are Bernoulli random variables with densities \( w(t) \) and \( e(t) \), respectively. For now it will suffice to say that \( w(t) = \phi(t/n, C_2(t)/n, C_3(t)/n) \) and \( e(t) = \psi(t/n, C_2(t)/n, C_3(t)/n) \) for some functions \( \phi, \psi \) to be specified in the course of the analysis. Note that \( \texttt{mtt} \) keeps running even after a contradiction (0-clause) has been generated and that if for some \( t_b, C_0(t_b) \neq \emptyset \) then \( C_0(t) \neq \emptyset \) for all \( t \geq t_b \).

Determine \( W(t) \) and \( E(t) \);
if \((W(t) = 0 \land C_2(t) \neq \emptyset)\)
then
- pick \((\ell_1 \lor \ell_2) \in C_2(t)\) u.a.r.;
  if \(E(t) = 0\)
    then gently-satisfy\((\ell_1, \ell_2)\)
    else just-satisfy \((\ell_1, \ell_2)\)
else repeat twice
  if there exist unit-clauses
    then pick a unit-clause \( \ell \) u.a.r. and satisfy it
  else pick u.a.r. an unset variable and assign it 0/1 u.a.r.

Two key points to keep in mind are: i) we will pick \( e(t) \) so small that we almost never perform just-satisfy, and ii) we will pick \( w(t) \) to “match” the rate at which 1-clauses are generated.
For a set of Boolean variables $V$ and an integer $k$ let $V_k$ denote the set of all $2^k\binom{|V|}{k}$ $k$-clauses on the variables of $V$ (whose literals are non-complementary and distinct). For integers $k,m$ let $D_k(V,m)$ denote the random set of $k$-clauses formed by selecting uniformly, independently and with replacement $m$ members of $V_k$. A key property that mTT shares with TT and the other four algorithms discussed in Section 3 is that it maintains uniform randomness.

Claim 1 (Uniform randomness) Assume that for some set $V$ and every $i$, $C_i(0) \overset{D}{=} D_i(V,m_i)$. Then, for every $i$ and every $t \geq 0$, conditional on $\mathcal{V}(t) = X$ and $C_i(t) = q$,

$$C_i(t) \overset{D}{=} D_i(X,q).$$

A formal proof of Claim 1, using the method of deferred decisions, is standard but tedious and we omit it in this extended abstract. The intuition behind the claim can be easily attained by imagining the following setting. Consider representing the input formula by using a row of $i$ cards for each $i$-clause, each card bearing the name of one literal. Assume that originally all the cards are “face-down”, i.e. the literal on each card is concealed and we never had an opportunity to see it. At the same time, assume that an intermediary knows precisely which literal is on each card. To interact with the intermediary we are allowed to either point at a card, or say the name of a variable. In response, if the card we point at carries literal $\ell$, the intermediary reveals (flips) all the cards carrying $\ell, \bar{\ell}$. Similarly, if we announce variable $v$, the intermediary reveals all the cards carrying $v, \bar{v}$. Now, the claim follows from observing that to run mTT or any of the other algorithms, it suffices for us to keep track of $\mathcal{V}(t)$ and to flip coins. Whenever we set a variable, we remove all the cards corresponding to dissatisfied literals and all the cards (some of them still concealed) corresponding to satisfied clauses. Thus, at the end of each round only “face-down” cards remain, containing only literals from $L(t)$.

As we mentioned earlier, our main tool for the analysis of mTT will be the main theorem of [36], stated as Theorem 3 in Appendix A for completeness. While the statement of the theorem is rather technical, the spirit of the theorem is that if a random process evolves “smoothly” in time, then w.h.p. it will remain very close to its “mean path” throughout its evolution. In particular, this mean path can be expressed as the solution of a system of differential equations associated with the process and thus it can either be recovered analytically, or bounded numerically. The idea of using differential equations to approximate discrete random processes goes back at least to Kurtz [26, 27]. It was first applied in the analysis of algorithms by Karp and Sipser [24].

The key idea which allows us to use Wormald’s theorem, is that one can afford to take care of the $1$-clauses in a “relaxed” way. That is, at the beginning of each round the algorithm flips a coin to decide if it will attempt to take care of $1$-clauses or not in this round. This makes the expected mean path can be expressed as the solution of a system of differential equations associated with the technical, the spirit of the theorem is that if a random process evolves “smoothly” in time, then

$$X = \mathbb{E}(F(t)).$$

Let $W(0), W(1), \ldots$ be a sequence of independent Bernoulli random variables with density $w(t)$, i.e. $W(t) = 1$ with probability $w(t)$, and 0 otherwise. For a given integer $s > 0$, let $Q(0), Q(1), \ldots$ be the sequence of random variables defined by $Q(0) = 0$ and $Q(t + 1) = \max (Q(t) - s \cdot W(t), 0) + F(t)$. 

6
Assume that there exist constants $a, b, c > 0$ such that for any fixed $j \geq i \geq 0$ and any $\delta > 0$,

$$\Pr \left[ \sum_{t=i}^{j} F(t) > (1 + \delta) \sum_{t=i}^{j} f(t) \right] < \exp \left( -a\delta^b \left( \sum_{t=i}^{j} f(t) \right)^c \right).$$

Then, if for some $\epsilon, \lambda > 0$ and all $t \geq 0$, we have

$$s(1 - \epsilon)w(t) > f(t) > \lambda,$$

there exists constants $C$ and $k$ depending on $a, b, c, s, \epsilon, \lambda$ such that for every $m \geq 1$,

$$\Pr \left[ \sum_{t=0}^{m-1} Q(t) > Cm \right] = O(m^{-2}) \quad \text{and} \quad \Pr \left[ \max_{0 \leq t < m} Q(t) > \log^k m \right] = O(m^{-2}).$$

5 The proof

Let $\epsilon = 10^{-6}$, $\zeta = 10^{-1}$ and $t_e = \lfloor 0.4n \rfloor$. Let $r^* = 3.1456$. To prove $r_3 > 3.145$ we will prove

Lemma 3 Let $F$ be a random formula resulting by taking the conjunction of $F_3(n, r^*n)$ and $F_2(n, en)$. There exists a choice of $\phi, \psi$ and constants $k, M$ such that if we run $m_{TT}$ on $F$ for $t_e$ rounds, then each of the following holds w.h.p.

$$C_1(t_e) < \log^b n,$$

$$\sum_{t=0}^{t_e} C_1(t) < Mn,$$

$$C_2(t_e) + C_3(t_e) < (1 - \zeta)(n - 2t_e).$$

Before proving Lemma 3 let us see how it implies Theorem 1.

Proof of Theorem 1. We will prove that $F$ is satisfiable with positive probability which, clearly, implies that $F_3(n, r^*n)$ is satisfiable with positive probability. By Corollary 1, this suffices.

Let $F_e$ be the random formula derived by: i) running $m_{TT}$ on $F$ for $t_e$ rounds, ii) removing any 0-clauses that might have been generated, and iii) randomly removing precisely one literal from any remaining 3-clause. By uniform randomness, $F_e$ is a conjunction of $F_2(n - 2t_e, C_2(t_e) + C_3(t_e))$ and $F_1(n - 2t_e, C_1(t_e))$, where $n - 2t_e = \Omega(n)$. Thus, combining Lemmata 1 and (3), (5) yields that $F_e$ is satisfiable w.h.p. Therefore, to prove that $F$ is satisfiable with positive probability it suffices to prove that $C_0(t_e) = 0$ with positive probability. (Here, and elsewhere we use the fact that if an event $A$ holds w.h.p. then for any event $B$, $\Pr[A \cap B] \geq \Pr[B] - o(1).$)

To bound $\Pr[C_0(t_e) = 0]$ from below we first observe that the probability of a 0-clause being generated in a given round $t$ is completely determined by $C_2(t), C_1(t)$ since each clause shrinks by at most one literal for each variable set. In particular, let $x, y$ be the two variables set in round $t$. Then, for a 0-clause to be generated in that round either there must be a 2-clause in $C_2(t)$ containing both $x$ and $y$ or at least one of $x, y$ must be the underlying variable for a literal in $C_1(t)$. Therefore, by uniform randomness, if $C_2(t) = q$ and $C_1(t) = s$ the probability that a 0-clause is not generated in round $t$ is at least

$$\left( 1 - \frac{1}{4^{(n-2t)/2}} \right)^q \left( 1 - \frac{1}{(n-2t)} \right)^s \geq \left( 1 - \frac{6}{n} \right)^{s+20},$$

7
where for the last inequality we use the fact $n - 2t \geq 0.2n$. As a result, conditional on

$$\sum_{t=0}^{t_e} C_1(t) < Mn \ ,$$

the probability of $C_0(t_e) = \emptyset$ is at least

$$\left(1 - \frac{6}{n}\right)^{(M+20)n} \geq e^{-6(M+20)} + o(1) > \rho(M) > 0 \ .$$

Since, by Lemma 3, (6) holds w.h.p., the lemma follows. \hfill \Box

To prove Lemma 3 we will trace the evolution of the random variables $C_i(t)$, $i = 2, 3$, for $0 \leq t \leq t_e$. In particular, the lemma will follow from Lemma 4 below (this last proof appears in Appendix B). Let $\delta = 10^{-7}$, and recall the definition of $\zeta, t_e$ and $F$ from Lemma 3. Also, recall that $\phi, \psi$ are the functions determining the density of $W(t), E(t)$ respectively.

**Lemma 4** There exists a choice of $\phi, \psi$ such that if we run $\text{mTT}$ on $F$ for $t_e$ rounds, then each of the following holds w.h.p.

$$\frac{C_2(t)}{n - 2t} \leq 2(1 - \delta)w(t) \ , \text{ for all } 0 \leq t \leq t_e, \quad (7)$$

$$C_2(t_e) + C_3(t_e) < (1 - \zeta)(n - 2t_e) \ . \quad \quad (8)$$

**Proof of Lemma 4.** We will apply Theorem 3 for random variables $C_2, C_3$ taking $m = n$ and noting that clearly $C_i(t) \leq r^*n$ for all $t$. With foresight, let us take the domain $D$ to be

$$D = \{(y_1, y_2, y_3) : 0 \leq y_1 \leq 0.41, y_2 \geq \epsilon/2, y_3 \geq \epsilon/2\} \ .$$

We will first determine the differential equation for $C_3$ and then for $C_2$.

- A clause leaves $C_3(t)$ during round $t$ iff it contains at least one of the variables set in round $t$. Thus, by uniform randomness, we see that conditional on $H(t)$, $C_3(t + 1) = C_3(t) - X$, where $X \sim \text{Bin}(C_3(t), p_3(t))$ and

$$p_3(t) \equiv \frac{2 \times 8(n-2t-2)}{8(n-2t)^2} + \frac{8}{n-2t} = \frac{6}{n-2t} + o(1/n) \ .$$

Thus, $\mathbf{E}(C_3(t + 1) - C_3(t) | H(t)) = -6C_3(t)/n(2) + o(1/n)$. Applying the Chernoff bound to $X$ implies that condition (ii) of Theorem 3 is satisfied immediately for $C_3$. Also, if $f_3(y_1, y_2, y_3) = -6y_3/(1 - 2y_1)$, then $\mathbf{E}(C_3(t + 1) - C_3(t) | H(t)) = f_3(t/n, C_2(t)/n, C_3(t)/n) + o(1)$. It is clear that $f_3$ is continuous and satisfies a Lipschitz condition on $D$ (i.e. since $y_1 = t/n \leq 0.41$). Thus, the differential equation and initial condition corresponding to $C_3$ is

$$\frac{dz_3}{ds} = -\frac{6z_3}{1 - 2s} \ , \quad z_3(0) = r^* \ . \quad \quad (9)$$

Solving (9), we get $z_3(s) = r^*(1 - 2s)^3$.

- The expected change of $C_2$ in round $t$ clearly depends on the values of $W(t), E(t)$.
precisely 1

This is because the "best possible" value assignment for \( v(\ell_1) \) and \( v(\ell_2) \) is \( (\ell_1 \lor \ell_2) \) in \( C_2(t) \) to pick and either gently-satisfy or just-satisfy. Moreover, every other clause in \( C_2(t) \) leaves \( C_2(t) \) during round \( t \) iff it contains at least one of \( v(\ell_1) \), \( v(\ell_2) \). Therefore, \( \ell_1 \lor \ell_2 \) is the unique clause in \( C_2(t) \) containing precisely one of \( v(\ell_1) \), \( v(\ell_2) \).}

\( \begin{align*}
p_2(t) & = 2 \times 4^{\binom{n-2t-2}{1}} + 4^{\binom{n-2t-2}{2}} = \frac{4}{n-2t} + o(1/n), \quad \text{and} \\
p_{32}(t) & = \frac{8^{\binom{n-2t-2}{2}}}{8^{\binom{n-2t}{3}}} = \frac{3}{n-2t} + o(1/n), \end{align*} \)

we see that conditional on \( H(t) \) and \( W(t) = 1 \), we have \( C_2(t+1) = C_2(t) - X + Y \), where \( X \overset{D}{=} \text{Bin}(C_2(t), p_2(t)) \) and \( Y \overset{D}{=} \text{Bin}(C_3(t), p_{32}(t)) \).

\( \begin{align*}
\text{(2*) If } W(t) = 1 \text{ then we first note that } (t/n, C_2(t)/n, C_3(t)/n) \in D \text{ implies } C_2(t)/n > \epsilon/3 > 0 \\
\text{and therefore that there exists } c = (\ell_1 \lor \ell_2) \in C_2(t) \text{ to pick and either gently-satisfy or just-satisfy.}
\end{align*} \)

Moreover, every other clause in \( C_3(t) \) leaves \( C_3(t) \) during round \( t \) iff it contains at least one of \( v(\ell_1) \), \( v(\ell_2) \). Therefore, \( \ell_1 \lor \ell_2 \) is the unique clause in \( C_3(t) \) containing precisely one of \( v(\ell_1) \), \( v(\ell_2) \). Since \( Z \overset{D}{=} \text{Bin}(C_3(t), 2p_{32}(t)) \), by applying the Chernoff bound for each of \( X, Y, T, Z \), we see that condition (ii) of Theorem 3 is satisfied for \( C_3(t) \).

Let \( U \) denote the random variable equal to the number of 3-clauses leaving \( C_3(t) \) to enter \( C_2(t+1) \) during round \( t \). If \( W(t) = 0 \) and \( E(t) = 1 \) then \( U \) behaves identically to the case \( W(t) = 1 \). To see this, note that in order to just-satisfy(\( \ell_1 \lor \ell_2 \)) the algorithm does not consider any clauses in \( C_3(t) \) and, therefore, the claim follows by the uniform randomness of \( c \).

To determine the distribution of \( U \) when \( W(t) = E(t) = 0 \) let \( E(t, \ell_1, \ell_2) \) be the set of all clauses in \( C_3(t) \) containing exactly one of \( \ell_1, \ell_1, \ell_2, \ell_2 \). Moreover, let \( X_1, X_2, X_3, X_4 \) be the random variables corresponding to the number of clauses in \( E(t, \ell_1, \ell_2) \) containing \( \ell_1, \ell_1, \ell_2, \ell_2 \), respectively. Finally, let us define the function \( \text{sb} : \mathbb{R}^4 \to \mathbb{R} \) by

\[ \text{sb}(w_1, w_2, w_3, w_4) = \min\{\min(w_1, w_2) + \max(w_3, w_4), \max(w_1, w_2) + \min(w_3, w_4)\} . \]

As is easy to see, \( \text{sb}(X_1, X_2, X_3, X_4) \) is the number of 3-clauses that will leave \( C_3(t) \) to enter \( C_2(t+1) \) if we need to assign the “second best” value assignment to \( v(\ell_1) \), \( v(\ell_2) \) in executing gently-satisfy. Note now that the probability of this last event is precisely 1/4 independently of anything else. This is because the “best possible” value assignment for \( v(\ell_1) \), \( v(\ell_2) \) is a function only of clauses in \( C_3(t) \) and therefore, by uniform randomness, that assignment fails to satisfy \( c \) with probability precisely 1/4. Hence, conditional on \( H(t) \) and \( W(t) = E(t) = 0 \), the expected value of \( U \) is

\[ \frac{3}{4} \times E(\text{min}(X_1, X_2) + \text{max}(X_3, X_4)) + \frac{1}{4} \times E(\text{sb}(X_1, X_2, X_3, X_4)) . \]

To determine the expectations in (10) we first note that while the random variables \( X_i \) are identically distributed, they are not independent; e.g. if \( X_1 = C_3(t) \) then \( X_2 = 0 \). Since, though, each variable

\( \begin{align*}
* \text{This is precisely the reason for which we add } en \text{ 2-clauses to the input formula: while, from } t = 0 \text{ and for a long time the rate at which 2-clauses are generated is substantially greater than the rate at which they disappear, if } C_2(0) = 0 \text{ then it is possible that in the first polylog}(n) \text{ rounds, } C_2(t) = 0 \text{ occurs a number of times; the extra } \Omega(n) \text{ 2-clauses provide a “cushion” guaranteeing that w.h.p. this does not happen.}
\end{align*} \)
appears on average in a constant number of clauses it is intuitively clear that as long as both \( t \) and \( C_3(t) \) are \( \Omega(n) \), the dependence between the \( X_i \) is minuscule. In particular, let \( p^* = \frac{3}{2(n-2t)} \) denote the probability that a clause in \( C_3(t) \) contains a given literal. Now, let \( X'_1, \ldots, X'_i \) be i.i.d. random variables with \( X'_t \overset{D}{=} \text{Bin}(C_3(t), p^*) \). It is not hard to prove that for \( (t/n, C_2(t)/n, C_3(t)/n) \in D \), the quantity in (10), i.e. the expected value of \( U \) conditional on \( H(t) \) and \( W(t) = E(t) = 0 \), is

\[
\frac{3}{4} \times 2E(\min(X'_1, X'_2)) + \frac{1}{4} \times E(s_b(X'_1, X'_2, X'_3, X'_4)) + o(1) . \tag{11}
\]

To handle the expectations in (11) we use the following lemma; its proof appears in Appendix C.

**Lemma 5** Let \( S_1, \ldots, S_4 \) be i.i.d. random variables with \( S_i \overset{D}{=} \text{Bin}(N, p) \), where \( Np = \lambda(1+o(1)) \) for some constant \( \lambda > 0 \) (asymptotically in \( N \)). Let \( Y = \min(S_1, S_2) \), and \( Z = s_b(S_1, S_2, S_3, S_4) \).

(a) There exist functions \( g, h : \mathbb{R} \to \mathbb{R} \) such that \( E(Y) = g(\lambda) + o(1) \) and \( E(Z) = h(\lambda) + o(1) \).

(b) Let functions \( \gamma, \chi \) be as defined in Appendix C. Then \( \gamma, \chi \) are continuous, satisfy a Lipschitz condition in \([0, \infty)\), and for all \( \lambda > 0 \),

\[
g(\lambda) < \gamma(\lambda) \leq \lambda \quad \text{and} \quad h(\lambda) < \chi(\lambda) \leq 2\lambda .
\]

Recall now that \( E(X'_1) = C_3(t)/(2(n-2t)) \). Therefore, using part (a) of Lemma 5 we get

\[
f_u(y_1, y_2, y_3) = \frac{3}{2}g\left(\frac{3y_3}{2(1-2y_1)}\right) + \frac{1}{4}h\left(\frac{3y_3}{2(1-2y_1)}\right)
\]

and \( g, h \) are as in Lemma 5.

Therefore, combining our estimates for the different cases we get

\[
E(C_2(t+1) - C_2(t) \mid H(t)) = \alpha(t/n, C_2(t)/n, C_3(t)/n) + o(1),
\]

where [writing \( \phi(y_1, y_2, y_3) \) as \( \phi \) and \( \psi(y_1, y_2, y_3) \) as \( \psi \), for clarity]

\[
\alpha(y_1, y_2, y_3) = (1 - \phi)\left(\psi\frac{3y_3}{1-2y_1} + (1 - \psi)f_u(y_1, y_2, y_3) - 1\right) + \phi\frac{3y_3}{1-2y_1} - \frac{4y_2}{1-2y_1} .
\]

Now, for \( \gamma, \chi \) as in Lemma 5, we define the function \( \psi \) to be

\[
\psi(y_1, y_2, y_3) = \frac{3}{2}\gamma\left(\frac{3y_3}{2(1-2y_1)}\right) + \frac{1}{4}\chi\left(\frac{3y_3}{2(1-2y_1)}\right) - f_u(y_1, y_2, y_3)
\]

so that [again writing \( \phi(y_1, y_2, y_3) \) as \( \phi \) for clarity] the function \( \alpha \) becomes

\[
\alpha(y_1, y_2, y_3) = (1 - \phi)\left(\frac{3}{2}\gamma\left(\frac{3y_3}{2(1-2y_1)}\right) + \frac{1}{4}\chi\left(\frac{3y_3}{2(1-2y_1)}\right) - 1\right) + \phi\frac{3y_3}{1-2y_1} - \frac{4y_2}{1-2y_1} .
\]

It is important to note that our choice of \( \psi \) is valid since, by Lemma 5, both enumerator and denominator in (12) are strictly positive, and the former is no greater than the latter.

It is not hard to see that the rate at which 1-clauses are generated is \( 2C_2(t)/(n-2t) + o(1) \) for all \( t \) (we show this in the proof of Lemma 3). Thus, as one might guess, the best choice for \( \phi \) is to define it so that for some arbitrarily small \( \theta > 0 \), and as long as \( C_2(t)/(n-2t) < 1 \)

\[
2 \cdot \phi(t/n, C_2(t)/n, C_3(t)/n) = (1 + \theta)\frac{2C_2(t)}{n-2t} .
\]
Therefore, for some (small) $\theta$ to be specified, we define

$$
\phi(y_1, y_2, y_3) = \min \left( \frac{(1 + \theta)y_2}{1 - 2y_1}, 1 \right).
$$

With this choice of $\phi$ and using $z_3(s) = r^*(1 - 2s)^3$, the differential equation and initial condition corresponding to $C_2$ is

$$
\frac{dz_2}{ds} = I_0 + I_1 - I_3, \quad z_2(0) = \epsilon,
$$

(13)

where,

$$
I_0 \equiv 1 - \min \left( \frac{(1 + \theta)z_2}{1 - 2s}, 1 \right) \left( 3\frac{r^*(1 - 2s)^2}{2} + \frac{1}{4} \chi \left( \frac{3r^*(1 - 2s)^2}{2} \right) - 1 \right),
$$

$$
I_1 \equiv \min \left( \frac{(1 + \theta)z_2}{1 - 2s}, 1 \right) 3r^*(1 - 2s)^2,
$$

$$
O \equiv \frac{4z_2}{1 - 2s}.
$$

It is straightforward to verify that the expression $I_0 + I_1 - O$ is continuous and satisfies a Lipschitz condition for $s \in [0, 1)$ and $z_2 \in [0, \infty)$ (therefore satisfying the condition of Theorem 3 on $D$).

Taking $\theta = 10^{-5}$, we solved the above differential equation numerically, using two different methods. The first one, easy to use but without guaranteed results, was by employing the numerical option in the `deSolve` function in Maple [34]. The second method was by using the interval arithmetic differential equation solver in [33]. The latter, partitions the domain of $s$ in intervals and returns guaranteed, i.e. provable, upper and lower bounds for the value of $z_2$ in each interval. (Maple remained inside those bounds out to six decimal digits.)

The lower bounds calculated using interval arithmetic give that indeed for all $s \in [0, 0.41]$, $z_2(s) > 0.9\epsilon$ and thus that $z_2$ does not leave the domain for $s \leq 0.41$. (For $z_3$ this follows immediately from the fact that $z_3$ is decreasing and $z_3(0.41) = 0.018.. > \epsilon$.) The upper bounds calculated for $z_2$ yield that indeed for all $s \in [0, 0.41]$, $z_2(s)/(1 - 2s) < (1 - \delta)/(1 + \theta)$ and therefore that indeed there exists a choice of $\phi, \psi$ such that w.h.p.

$$
\frac{C_2(t)}{n - 2t} < 2(1 - \delta)w(t), \quad \text{for all } 0 \leq t \leq t_e.
$$

Finally, the upper bound $z_2(0.4) < 0.13$ along with $z_3(0.4) = 0.025..$ imply that w.h.p.

$$
C_2(t_e) + C_3(t_e) < (1 - \zeta)(n - 2t_e).
$$

\[\square\]

A Appendix

In the statement of Theorem 3, below, asymptotics denoted by o and O, are for \( n \to \infty \) but uniform over all other variables. In particular, “uniformly” refers to the convergence implicit in the o() terms. For a random variable \( X \), we say \( X = o(f(n)) \) always if \( \max\{x : \Pr[X = x] \neq 0\} = o(f(n)) \).

We say that a function \( f \) satisfies a Lipschitz condition on \( D \subseteq \mathbb{R}^j \) if there exists a constant \( L > 0 \) such that \( |f(u_1, \ldots, u_j) - f(v_1, \ldots, v_j)| \leq L \sum_{i=1}^{j} |u_i - v_i| \), for all \((u_1, \ldots, u_j)\) and \((v_1, \ldots, v_j)\) in \( D \).

**Theorem 3** ([36]) Let \( Y_i(t) \) be a sequence of real-valued random variables, \( 1 \leq i \leq k \) for some fixed \( k \), such that for all \( i \), all \( t \) and all \( n \), \( |Y_i(t)| \leq Cn \) for some constant \( C \). Let \( H(t) \) be the history of the sequence, i.e. the matrix \( \langle \tilde{Y}(0), \ldots, \tilde{Y}(t) \rangle \), where \( \tilde{Y}(t) = (Y_1(t), \ldots, Y_k(t)) \).

Let \( I = \{(y_1, \ldots, y_k) : \Pr[\tilde{Y}(0) = (y_1n, \ldots, y_kn)] \neq 0 \text{ for some } n\} \). Let \( D \) be some bounded connected open set containing the intersection of \{ \((s, y_1, \ldots, y_k) : s \geq 0\) \} with a neighborhood of \{(0, y_1, \ldots, y_k) : (y_1, \ldots, y_k) \in I\}.

Let \( f_i : \mathbb{R}^{k+1} \to \mathbb{R}, 1 \leq i \leq k, \) and suppose that for some \( m = m(n) \),

(i) for all \( i \) and uniformly over all \( t < m \),

\[
\mathbb{E}(Y_i(t+1) - Y_i(t)|H(t)) = f_i(t/n, Y_0(t)/n, \ldots, Y_k(t)/n) + o(1), \text{ always;}
\]

(ii) for all \( i \) and uniformly over all \( t < m \),

\[
\Pr\left[|Y_i(t+1) - Y_i(t)| > n^{1/5} |H(t)|\right] = o(n^{-3}), \text{ always;}
\]

(iii) for each \( i \), the function \( f_i \) is continuous and satisfies a Lipschitz condition on \( D \).

Then

(a) for \((0, \hat{z}(0), \ldots, \hat{z}(k)) \in D\) the system of differential equations

\[
\frac{dz_i}{ds} = f_i(s, z_0, \ldots, z_k), \quad 1 \leq i \leq k
\]

has a unique solution in \( D \) for \( z_i : \mathbb{R} \to \mathbb{R} \) passing through \( z_i(0) = \hat{z}(i) \), \( 1 \leq i \leq k \), and which extends to points arbitrarily close to the boundary of \( D \);

(b) almost surely

\[
Y_i(t) = z_i(t/n) \cdot n + o(n),
\]

uniformly for \( 0 \leq t \leq \min\{\sigma n, m\} \) and for each \( i \), where \( z_i(s) \) is the solution in (a) with \( \hat{z}(i) = Y_i(0)/n \), and \( \sigma = \sigma(n) \) is the supremum of those \( s \) to which the solution can be extended.

**Note:** The theorem remains valid if the reference to “always” in (i),(ii) is replaced by the restriction to the event \((t/n, Y_0(t)/n, \ldots, Y_k(t)/n) \in D\).

---

\(^1\) That is, after taking a ball around the set \( I \), we require \( D \) to contain the part of the ball in the halfspace corresponding to \( s = t/n \geq 0 \).
B Appendix

Proof of Lemma 2. Let us say that \( Q \) returns at step \( t \), if \( Q(t) < s \) and \( Q(t-1) \geq s \); let us say that \( Q \) departs at step \( t \), if \( Q(t) \geq s \) and \( Q(t-1) < s \). For \( j \geq 0 \), let \( B_j = t_j^t - t_j^d \), where \( t_j^t, t_j^d > 0 \) are the steps corresponding to the \( j \)th return and the \( j \)th departure, respectively. For \( t \geq 0 \), let \( h^r(t) = \min\{j : t_j^r \geq t\} \), i.e. the index of the first return occurring no earlier than \( t \).

We first observe that for any values (realizations) \( b_0, b_1, \ldots \) of the random variables \( B_j \),

\[
\sum_{t=m-1}^m Q(t) \leq \sum_{j=0}^{h^r(m-1)} \frac{1}{2} b_j (s(b_j + 1) - 2) \leq s \sum_{j=0}^{h^r(m-1)} b_j^2 ,
\]

since \( Q \) decreases by at most \( s \) in each step and, therefore, cannot exceed \( s(b_j + 1) - 2 \) between \( t_j^d \) and \( t_j^t \) (the “worst case” occurs when \( Q \) “shoots up” from below \( s \) and then continually drops).

For each \( i = 0, \ldots, s-1 \) and \( t = 0, 1, \ldots \), let us define two sequences of random variables \( W_t^i(z), F_t^i(z) \), \( z \geq 0 \), by \( W_t^i(z) \overset{D}{=} W(t + z) \) and \( F_t^i(z) \overset{D}{=} F(t + z) \). Now, for each \( i = 0, \ldots, s-1 \) and \( t = 0, 1, \ldots \), we define the sequence of ransom variables \( D_t^i(z) \), as follows: \( D_t^i(0) = i \) and \( D_t^i(z + 1) = \max(D_t^i(z) - s \cdot W_t^i(z), 0) + F_t^i(z) \). Finally, let \( b_i^t = \min\{z > t : D_t^i(z) < s\} \). If we now consider for each sequence \( D_t^i \) its subsequence from \( z = 0 \) to \( z = b_i^t \) we see that \( Q \) is realized by some concatenation of these subsequences. Therefore,

\[
\sum_{t=0}^{m-1} Q(t) \leq s \sum_{i=0}^{s-1} \sum_{t=0}^{m-1} (b_i^t)^2 \equiv s \cdot Z .
\]

To get a handle on the distribution of \( Z \) we will bound \( \Pr[b_i^t \geq x] \) for each \( i, t \) and integer \( x \geq 0 \). For this, we first observe that if for some \( l > 0 \),

\[
\sum_{z=0}^l F_t^i(z) < s \sum_{z=0}^l W_t^i(z) \tag{14}
\]

then there exists \( 0 < z \leq l \) such that \( D_t^i(z) < s \). So, for a fixed \( l \), the probability that (14) does not hold is bounded by

\[
\Pr \left[ \sum_{z=0}^l F_t^i(z) > (1 + \epsilon / 3) \sum_{z=0}^l f(t + z) \right] + \Pr \left[ \sum_{z=0}^l W_t^i(z) < (1 - \epsilon / 3) \sum_{z=0}^l w(t + z) \right] , \tag{15}
\]

for if neither of the events in (15) occurs (1) implies that (14) holds.

Now, using the fact that both \( w(t), f(t) \) are bounded away from 0 for all \( t \), along with the given tail bound for \( \sum F(t) \), and the Chernoff bound for \( \sum W(t) \), we get that there exist \( \eta, \zeta > 0 \) depending on \( a, b, c, s, \epsilon, \lambda \) such that for all \( i, t \)

\[
\Pr[b_i^t \geq x] < \exp(-\eta x^\zeta) . \tag{16}
\]

Thus, \( Z \) is the sum of \( sm \) independent random variables \( R_0, \ldots, R_{sm-1} \) (where \( R_{st+i} = (b_i^t)^2 \)) such that for every integer \( x \geq 0 \), \( \Pr[R_j \geq x^2] \leq \exp(-\eta x^\zeta) \). Hence, \( E[R_j] \) is bounded by a constant as

\[
E[R_j] = \sum_{y=0}^{\infty} \Pr[R_j > y] \leq \sum_{y=0}^{\infty} \exp(-\eta(\sqrt{y})^\zeta) < K(\eta, s, \zeta) \equiv K .
\]
Let \([k = 3/\zeta]\). To conclude the proof we let

\[
R'_j = \begin{cases} R_j, & \text{if } R_j \leq \log^k m \\ 0, & \text{if } R_j > \log^k m \end{cases}
\]

and

\[
Z' = \sum_{j=0}^{sm-1} R'_j.
\]

We first observe that \(\Pr[Z \neq Z'] \leq sm \Pr[R_j \neq R'_j] = O(m^{-2})\) (we take \(O(m^{-2})\) as it is sufficient for our purposes). This immediately proves our claim regarding the probability of \(Q\) exceeding \(\log^k m\). Moreover, \(\mathbb{E}[Z'] \leq \mathbb{E}[Z] \leq Km\). Thus, for \(L = L(a, b, c, s, \epsilon, \lambda) = 2K\) we get

\[
\Pr[Z > Lm] \leq \Pr[Z' > 2Km] + O(m^{-2}) \leq \Pr[Z' - \mathbb{E}[Z'] > Km] + O(m^{-2}).
\]

To bound the probability in (17) we consider the martingale sequence formed by the random variables \(T_0, T_1, T_2, \ldots, T_{sm-1}\) where \(T_0 = \mathbb{E}[Z']/\log^k m\) and \(T_{j+1}\) is \(1/\log^k m\) times the conditional expectation of \(Z'\) given the values of \(R'_0, \ldots, R'_j\). Applying Azuma’s inequality, yields

\[
\Pr[Z' - \mathbb{E}[Z'] > Km] < 2 \exp \left( - \frac{K^2 m}{2(\log m)^2} \right) = O(m^{-2}).
\]

Thus, taking \(C = sL\) yields the desired bound on \(\sum_{t=0}^{m-1} Q(t)\). \(\square\)

**Proof of Lemma 3.** Since, by Lemma 4, (5) holds w.h.p. it will suffice to prove that each of (3) and (4) hold w.h.p. Let \(\text{flow}_1(t)\) be the random variable equal to the number of clauses that shrink to length 1 during round \(t\). Then, \(C_1(0) = 0\) and it is easy to see that for all \(t \geq 0\),

\[
C_1(t + 1) \leq \max(C_1(t) - 2 \cdot W(t), 0) + \text{flow}_1(t).
\]

Let \(G(t)\) be defined by \(G(0) = 0\) and \(G(t + 1) = \max(G(t) - 2 \cdot W(t), 0) + \text{flow}_1(t)\), for \(t \geq 0\). An easy induction shows that \(G(t) \geq C_1(t)\) for all \(t\). Now, let

\[
p_{21}(t) = \frac{4^{(n-2t-2)/2}}{4^{(n-2t)/2}} = \frac{2}{n - 2t} + o(1)
\]

and

\[
p_{31}(t) = \frac{2^{(n-2t-2)/3}}{8^{(n-2t)/3}} = \frac{3}{2(n - 2t)^2} + o(1).
\]

By uniform randomness it follows that \(\text{flow}_1(t) = \text{flow}_{21}(t) + \text{flow}_{31}(t)\), where

\[
\text{flow}_{21}(t) \overset{D}{=} \text{Bin}(X(t), p_{21}(t)),
\]

\[
\text{flow}_{31}(t) \overset{D}{=} \text{Bin}(C_3(t), p_{31}(t)),
\]

and \(X_2(t)\) is either \(C_2(t)\) or \(C_2(t) - 1\).

Using the above facts and Lemma 4 it is straightforward to construct, via a simple coupling, a random variable \(Q(t)\) which i) satisfies the conditions of Lemma 2 by construction, and such that ii) w.h.p. \(C_1(t) \leq Q(t)\) for all \(0 \leq t \leq t_\epsilon\). The lemma then follows by applying Lemma 2 for \(Q\) and using the fact that if events \(A\) and \(B\) each hold w.h.p. then so does the event \(A \cap B\). \(\square\)
C Appendix

Definition of function $\gamma$: $\gamma$ is the piecewise linear function defined by $\gamma(0) = 0$, $\gamma(1) = 0.476223$, $\gamma(3/2) = 0.840260$, $\gamma(2) = 1.228495$, $\gamma(5/2) = 1.631218$, $\gamma(3) = 2.043874$, $\gamma(7/2) = 2.463906$, $\gamma(4) = 2.889703$, $\gamma(9/2) = 3.320170$, $\gamma(5) = 3.754520$, $\gamma(6) = 6$; $\gamma(\lambda) = \lambda$ for $\lambda \geq 6$.

Definition of function $\chi$: to define $\chi$ let $z(\lambda) = \frac{1}{100}(2\lambda^2 + 174\lambda - 22)$. Then, for $\lambda \in [0, 1/2]$, $\chi(\lambda) = 2\lambda$; for $\lambda \in [1/2, 1]$, $\chi(\lambda) = 2(z(1) - 1)\lambda + 2 - z(1)$; for $\lambda \in [1, 5]$, $\chi(\lambda) = z(\lambda)$; for $\lambda \in [5, 6]$, $\chi(\lambda) = (12 - z(5))\lambda + 6z(5) - 60$; $\chi(\lambda) = 2\lambda$, for $\lambda \geq 6$.

Proof of Lemma 5.

a) Let $\text{Po}(\lambda)$ denote the Poisson random variable with mean $\lambda$. Let $\text{Pr}[\text{Po}(\lambda) = i] = P(\lambda; i)$. Using the standard approximation of the Binomial random variable with the corresponding Poisson random variable it is easy to show that

\[ \mathbb{E}(Y) = \sum_{i=0}^{\infty} \sum_{j=0}^{\infty} P(\lambda; i)P(\lambda; j) \min(i, j) + o(1) \equiv g(\lambda) + o(1) \quad \text{and} \]

\[ \mathbb{E}(Z) = \sum_{i=0}^{\infty} \sum_{j=0}^{\infty} \sum_{k=0}^{\infty} P(\lambda; i)P(\lambda; j)P(\lambda; k) \sum_{l=0}^{\infty} \text{sb}(i, j, k, l) + o(1) \equiv h(\lambda) + o(1) \quad \text{(20)} \]

b) The fact that $\gamma, \chi$ are continuous and satisfy a Lipschitz condition on $[0, \infty)$ is trivial to verify by inspection. Similarly, for the facts $\gamma(\lambda) \leq \lambda$ and $\chi(\lambda) \leq 2\lambda$, for all $\lambda \geq 0$.

From the fact that the inequalities $\min(i, j) \leq (i+j)/2$ and $\text{sb}(i, j, k, l) \leq (i+j+k+l)/2$ are strict for certain $i, j$ we get that for all $\lambda > 0$, $g(\lambda) < \lambda$ and $h(\lambda) < 2\lambda$. This yields that for $\lambda > 6$, $g(\lambda) < \gamma(\lambda)$ and $h(\lambda) < \chi(\lambda)$. Therefore, we are left to prove $g(\lambda) < \gamma(\lambda)$ and $h(\lambda) < \chi(\lambda)$ for $\lambda \in [0, 6]$.

To show that $\gamma$ strictly bounds $g$ from above we will use the following fact (due to Diaconis, see p. 293 in [28]): if $W_1, \ldots, W_k$ are i.i.d. Poisson random variables with mean $\lambda$ and $\phi : \mathbb{R}^k \to \mathbb{R}$ is a convex function, then $\mathbb{E}(\phi(W_1, \ldots, W_k))$ is a convex function of $\lambda$. Since $\min$ is convex, it follows that $g$ is bounded from above by any piecewise linear function defined by upper bounds for values of $g$. To get such bounds, we use that for any $u \geq 0$,

\[ g(\lambda) \leq \lambda - \sum_{i=0}^{u} \sum_{j=0}^{u} P(\lambda; i)P(\lambda; j) \left( \frac{i+j}{2} - \min(i, j) \right) \]

\[ \equiv \lambda - q_u(\lambda) \quad \text{(21)} \]

Now, $q_u$ can be bounded numerically with guaranteed accuracy using interval arithmetic. For this, we used the function shake of Maple [34]. The values defining $\gamma$ were derived by substituting the returned lower bound for $q_{u0}$ at each respective point to (21), dividing by $1 - 10^{-8}$, and rounding up.

For $h$ matters are complicated by the fact that $\text{sb}$ is not a convex function. Analogously to $g$, though, we note that for any $u \geq 0$, $h$ is bounded by

\[ 2\lambda - \sum_{i=0}^{u} \sum_{j=0}^{u} \sum_{k=0}^{u} \sum_{l=0}^{u} P(\lambda; i)P(\lambda; j)P(\lambda; k)P(\lambda; l) \left( \frac{i+j+k+l}{2} - \text{sb}(i, j, k, l) \right) \]

\[ \equiv 2\lambda - h_u(\lambda) \quad \text{.} \]

By inspection, i.e. plotting, we observed that $z(\lambda)$ strictly bounds $2\lambda - h_{15}(\lambda)$ from above in $[1/2, 6]$. To prove this we used interval arithmetic to bound the range of $z(\lambda) - 2\lambda + h_{15}(\lambda)$ from below for $\lambda \in [1/2, 6]$; we got a lower bound of $8.32603 \times 10^{-7}$. For $(0, 1/2]$ the fact $h(\lambda) < \chi(\lambda)$ follows from the fact $h(\lambda) < 2\lambda$ for all $\lambda > 0$ and the definition of $\chi$. \hfill \Box
