ABSTRACT

Standard generalized additive models (GAMs) usually model the dependent variable as a sum of univariate models. Although previous studies have shown that standard GAMs can be interpreted by users, their accuracy is significantly less than more complex models that permit interactions.

In this paper, we suggest adding selected terms of interacting pairs of features to standard GAMs. The resulting models, which we call GA²M-models, for Generalized Additive Models plus Interactions, consist of univariate terms and a small number of pairwise interaction terms. Since these models only include one- and two-dimensional components, the components of GA²M-models can be visualized and interpreted by users. To explore the huge (quadratic) number of pairs of features, we develop a novel, computationally efficient method called FAST for ranking all possible pairs of features as candidates for inclusion into the model.

In a large-scale empirical study, we show the effectiveness of FAST in ranking candidate pairs of features. In addition, we show the surprising result that GA²M-models have almost the same performance as the best full-complexity models on these datasets. Thus this paper postulates that for many problems, GA²M-models can yield models that are both intelligible and accurate.

1.2.6 [Computing Methodologies]: Learning—Induction

Keywords

classification, regression, interaction detection

1. INTRODUCTION

Many machine learning techniques such as boosted or bagged trees, SVMs with RBF kernels, or deep neural nets are powerful models for high-dimensional prediction problems. However, due to their complexity, the resulting models are hard to interpret for the user. But in many applications, intelligibility is as important as accuracy [19], and thus building models that users can understand is a crucial requirement.

Generalized additive models (GAMs) are the gold standard for intelligibility when only univariate terms are considered [13] [19]. Standard GAMs have the form

\[ g(E[y]) = \sum f_i(x_i), \]

where \( g \) is the link function. Standard GAMs are easy to interpret since users can visualize the relationship between the univariate terms of the GAM and the dependent variable through a plot \( f_i(x_i) \) vs. \( x_i \). However there is unfortunately a significant gap between the performance of the best standard GAMs and full complexity models [19]. In particular, Equation 1 does not model any interactions between features, and it is this limitation that lies at the core of the lack of accuracy of standard GAMs as compared to full complexity models.

\[ g(E[y]) = \sum f_i(x_i) + \sum f_{ij}(x_i, x_j); \]

We call the resulting model class Generalized Additive Models plus Interactions, or short GA²Ms.

The main challenge in building GA²Ms is the large number of pairs of features to consider. We thus only want to include “true” interactions that pass some statistical test. To this end, we focus on problems with up to thousands of features since for truly high dimensional problems (e.g., millions of features), it is almost intractable to test all possible pairwise interactions (e.g., trillions of feature pairs).

Existing approaches for detecting statistical interactions can be divided into two classes. One class of methods di-
rectly models and compares the interaction effects and additive effects [10, 11, 15, 25]. One drawback of these methods is that spurious interactions may be reported over low-density regions [15]. The second class of methods measures the performance drop in the model if certain interaction is not included; they compare the performance between restricted and unrestricted models, where restricted models are not allowed to model an interaction in question [22]. Although this class of methods does not suffer from the problem of low-density regions, they are computationally extremely expensive even for pairwise interaction detection.

Our second contribution in this paper is to scale the construction of GA\textsuperscript{2}Ms by proposing a novel, extremely efficient method called FAST to measure and rank the strength of the interaction of all pairs of variables. Our experiments show that FAST can efficiently rank all pairwise interactions close to a ground truth ranking.

Our third contribution is an extensive empirical evaluation of GA\textsuperscript{2}M-models. Surprisingly, on many of the datasets included in our study, the performance of GA\textsuperscript{2}M-models is close and sometimes better than the performance of full-complexity models. These results indicate that GA\textsuperscript{2}M-models not only make a significant step in improving accuracy over standard GAMs, but in some cases they actually come all the way to the performance of full-complexity models. The performance may be due to the difficulty of estimating intrinsically high dimensional functions from limited data, suggesting that the bias associated with the GA\textsuperscript{2}M structure is outweighed by a drop in variance. We also demonstrate that the resulting models are intelligible through a case study.

In this paper we make the following contributions:

- We introduce the model class GA\textsuperscript{2}M.
- We introduce our new method FAST for efficient interaction detection. (Section 2)
- We show through an extensive experimental evaluation that (1) GA\textsuperscript{2}M-models have accuracy comparable to full-complexity models; (2) FAST accurately ranks interactions as compared to a gold standard; and (3) FAST is computationally efficient. (Section 4)

We start with a problem definition and a survey of related work in Sections 2 and 3.

2. PROBLEM DEFINITION

Let \( D = \{(x_i, y_i)\}_{i=1}^N \) denote a dataset of size \( N \), where \( x_i = (x_{i1}, ..., x_{in}) \) is a feature vector with \( n \) features and \( y_i \) is the response. Let \( x = (x_1, ..., x_n) \) denote the variables or features in the dataset. For \( u = \{1, ..., n\} \), we denote by \( x_u \) the subset of variables whose indices are in \( u \). Similarly, \( x_{-u} \) will indicate the variables with indices not in \( u \). To simplify notation, we denote \( U_1 = \{i | 1 \leq i \leq n\} \), \( U_2 = \{i, j | 1 \leq i < j \leq n\} \), and \( U = U_1 \cup U_2 \), i.e., \( U \) contains all indices for all features and pairs of features.

For any \( u \in U \), let \( H_u \) denote the Hilbert space of Lebesgue measurable functions \( f_u(x_u) \), such that \( E[f_u] = 0 \) and \( E[f^2_u] < \infty \), equipped with the inner product \( \langle f_u, f'_u \rangle = E[f_u f'_u] \). Let \( H^1 = \sum_{u \in U} H_u \) denote the Hilbert space of functions that has additive form \( F(x) = \sum_{u \in U} f_u(x_u) \) on univariate components; we call those components shape functions [10]. Similarly let \( H = \sum_{u \in U} H_u \) denote the Hilbert space of functions of \( x = (x_1, ..., x_n) \) that has additive form \( F(x) = \sum_{u \in U} f_u(x_u) \) on both one- and two-dimensional shape functions. Models described by sums of low-order components are called generalized additive models (GAMs), and in the remainder of the paper, we use GAMs to denote models that only consist of univariate terms.

We want to find the best model \( F \in \mathcal{H} \) that minimizes the following objective function:

\[
\min_{F \in \mathcal{H}} E[L(y, F(x))],
\]

where \( L(\cdot, \cdot) \) is a non-negative convex loss function. When \( L \) is the squared loss, our problem becomes a regression problem, and if \( L \) is logistic loss function, we are dealing with a classification problem.

3. EXISTING APPROACHES

3.1 Fitting Generalized Additive Models

Terms in GAMs can be represented by a variety of functions, including splines [24], regression trees, or tree ensembles [9]. There are two popular methods of fitting GAMs: Backfitting [13] and gradient boosting [10]. When the shape function is spline, fitting GAMs reduces to fitting generalized linear models with different bases, which can be solved by least squares or iteratively reweighted least squares [25].

Spline-based methods become inefficient when modeling higher order interactions because the number of parameters to estimate grows exponentially; tree-based methods are more suitable in this case. Standard additive modeling only involves modeling individual features (also called feature shaping). Previous research showed that gradient boosting with ensembles of shallow regression trees is the most accurate method among a number of alternatives [10].

3.2 Interaction Detection

In this section, we briefly review existing approaches to interaction detection.

ANCOVA. An additive model is fit with all pairwise interaction terms [13] and the significance of interaction terms is measured through an analysis of variance (ANOVA) test [25]. The corresponding p-value for each pair can then be computed; however, this requires the computation of the full model, which is prohibitively expensive.

Partial Dependence Function. Friedman and Popescu proposed the following statistic to measure the strength of pairwise interactions,

\[
H^2_{ij} = \frac{\sum_{k=1}^N \left( \hat{F}_{ij}(x_{ki}, x_{kj}) - F(x_{ki}) - F(x_{kj}) \right)^2}{\sum_{k=1}^N \hat{F}^2_{ij}(x_{ki}, x_{kj})}
\]

where \( \hat{F}_{ij}(x_u) = E_{x_{-u}}[F(x_{-u}, x_u)] \) is the partial dependence function (PDF) [10, 11] and \( F \) is a complex multi-dimensional function learned on the dataset. Computing \( \hat{F}_{ij}(x_u) \) on the whole dataset is expensive, thus one first specifies a subset of size \( m \) on which to compute \( \hat{F}_{ij}(x_u) \). The complexity is then \( O(m^2) \). However, since partial dependence functions are computed based on uniform sampling, they may detect spurious interactions over low-density regions [15].

GUIDE. GUIDE tests pairwise interactions based on the \( \chi^2 \) test [18]. An additive model \( F \) is fit in \( H^1 \) and residuals are obtained. To detect interactions for \( (x_i, x_j) \), GUIDE divides the \( (x_i, x_j) \)-space into four quadrants by splitting the range of each variable into two halves at the sample median.
Then GUIDE constructs a $2 \times 4$ contingency table using the residual signs as rows and the quadrants as columns. The cell values in the table are the number of “+’s” and “−’s” in each quadrant. These counts permit the computation of a $p$-value to measure the interaction strength of a pair. While this might be more robust to outliers, in practice it is less powerful than the method we propose.

**Grove.** Sorokina et al. proposed a grove-based method to detect statistical interactions [22]. To measure the strength of a pair $(x_i, x_j)$, they build both the restricted model $R_{ij}(x)$ and unrestricted model $F(x)$, where $R_{ij}(x)$ is prevented from modeling an interaction $(x_i, x_j)$:

$$R_{ij}(x) = f_i(x_1, \ldots, x_{i-1}, x_{i+1}, \ldots, x_n) + f_j(x_1, \ldots, x_{j-1}, x_{j+1}, \ldots, x_n). \tag{5}$$

To correctly estimate interaction strength, such method requires a model to be highly predictive when certain interaction is not allowed to appear, and therefore many learning algorithms are not applicable (e.g., bagged decision trees). To this end, they choose to use Additive Grove [21].

They measure the performance as standardized root mean squared error (RMSE) and quantify the interaction strength $I_{ij}$ by the difference between $R_{ij}(x)$ and $F(x)$,

$$stRMSE(F(x)) = \frac{RMSE(F(x))}{STD(F^*(x))} \tag{6}$$

$$I_{ij} = stRMSE(R_{ij}(x)) - stRMSE(F(x)) \tag{7}$$

where $STD(F^*(x))$ is calculated as standard deviation of the response values in the training set. The ranking of all pairs can be generated based on the strength $I_{ij}$.

To handle correlations among features, they use a variant of backward elimination [12] to do feature selection. Although Grove is accurate in practice, building restricted and unrestricted models are computationally expensive and therefore this method is almost infeasible for large high dimensional datasets.

4. OUR APPROACH

For simplicity and without loss of generality, we focus in this exposition on regression problems. Since there are $O(n^2)$ pairwise interactions, it is very hard to detect pairwise interactions when $n$ is large. Therefore we propose a framework using greedy forward stagewise selection strategy to build the most accurate model in $\mathcal{H}$.

Algorithm 1 summarizes our approach called GA2M. We maintain two sets $S$ and $Z$, where $S$ contains the selected pairs so far and $Z$ is the set of the remaining pairs (Line 1-2). We start with the best additive model $F$ so far in Hilbert space $\mathcal{H}^1 + \sum_{u \in S} \mathcal{H}_u$ (Line 4) and detect interactions on the residual $R$ (Line 5). Then for each pair in $Z$, we build an interaction model on the residual $R$ (Line 6-7). We select the best interaction pair and include it in $S$ (Line 9-10). We then repeat this process until there is no gain in accuracy.

Note that Algorithm 1 will find an overcomplete set $S$ by the greedy nature of the forward selection strategy. When features are correlated, it is also possible that the algorithm includes false pairs. For example, consider the function in Example 1. If $x_1$ is highly correlated with $x_3$, then $(x_1, x_2)$ may look like an interaction pair, and it may be included in $S$ before we select $(x_2, x_3)$. But since we will refit the model every time we include a new pair, it is expected that $F$ will perfectly model $(x_2, x_3)$ and therefore $(x_1, x_2)$ will become a less important term in $F$.

For large high-dimensional datasets, however, Algorithm 1 is very expensive for two reasons. First, fitting interaction models for $O(n^2)$ pairs in $Z$ can be very expensive if the model is non-trivial. Second, every time we add a pair, we need to refit the whole model, which is also very expensive for large datasets. As we will see in Section 4.4 and Section 4.2, we will relax some of the constraints in Algorithm 1 to achieve better scalability while still staying accurate.

4.1 Fast Interaction Detection

Consider the conceptual additive model in Equation 2 given a pair of variables $(x_i, x_j)$ we wish to measure how much benefit we can get if we model $f_{ij}(x_i, x_j)$ instead of $f_i(x_i) + f_j(x_j)$. Since we start with shaping individual features and always detect interactions on the residual, $f_i(x_i) + f_j(x_j)$ are presumably modeled and therefore we only need to look at the residual sum of squares (RSS) for the interaction model $f_{ij}$. The intuition is that when $(x_i, x_j)$ is a strong interaction, modeling $f_{ij}$ can significantly reduce the RSS. However, we do not wish to fully build $f_{ij}$ since this is a very expensive operation; instead we are looking for a cheap substitute.

4.1.1 Overview

Our idea is to build an extremely simple model for $f_{ij}$ using cuts on the input space of $x_i$ and $x_j$, as illustrated in Figure 1. The simplest model we can build is to place one cut on each variable, i.e., we place one $c_i$ and one cut $c_j$. We now describe how to build $f_{ij}$ given $c_i$ and $c_j$.
c_j on x_1 and x_2, respectively. Those cuts are parallel to the axes. The interaction predictor T_{ij} is constructed by taking the mean of all points in each quadrant. We search for all possible (c_i, c_j) and pick the best T_{ij} with the lowest RSS, which is assigned as weight for (x_i, x_j) to measure the strength of interaction.

4.1.2 Constructing Predictors

Naive implementation of FAST is straightforward, but careless implementation has very high complexity since we need to repeatedly build a lot of T_{ij} for different cuts. The key insight for faster version of FAST is that we do not need to scan through the dataset each time to compute T_{ij} and compute its RSS. We show that by using very simple bookkeeping data structures, we can greatly reduce the complexity.

Let dom(x_i) = \{v_i^1, ..., v_i^d_i\} be a sorted set of possible values for variable x_i, where d_i = |dom(x_i)|. Define H_i^w(v) as the sum of targets when x_i = v, and define H_i^w(v) as the sum of weights (or counts) when x_i = v. Intuitively, these are the standard histograms when constructing regression trees. Similarly, we define CH_i^w(v) = \sum_{u \leq v} H_i^w(u) and CH_i^w(v) = \sum_{u \geq v} H_i^w(u). Accordingly, define CH_i^w(v) = \sum_{u > v} H_i^w(u) = CH_i^w(v_i^d_i) - CH_i^w(v) and define CH_i^w(v) = \sum_{u < v} H_i^w(u) = CH_i^w(v_i^1) - CH_i^w(v). Furthermore, define H_{ij}^w(u, v) and H_{ij}^w(u, v) as the sum of targets and the sum of weights, respectively, when (x_i, x_j) = (u, v).

Consider again the input space for (x_i, x_j), we need a quick way to compute the sum of targets and sum of weights for each quadrant. Figure 2 shows an example for computing sum of targets on each quadrant. The interaction predictor T_{ij} is constructed by taking the mean of all points in each quadrant. Given the above notations, for each quadrant. Figure 2 shows an example for computing sum of targets in that quadrant.

The marginal cumulative histograms are constructed by taking the mean of all points in each quadrant. Given the above notations, for each quadrant. Figure 2 shows an example for computing sum of targets in that quadrant.

Algorithm 2 describes how to compute the lookup table L_i. We focus on computing quadrant a and other quadrants can be easily computed, which is handled by subroutine ComputeValues. Given H_{ij}, we first compute as for the first row of L_i (Line 3-5). Let a[p][q] denote the value for cuts (p, q). Note a[p][q] = a[p-1][q] + \sum_{u \leq q} H_{ij}^w(v_i^u, v_j^q). Thus we can efficiently compute the rest of the lookup table row by row (Line 6-11).

Once we have L_i and L_w, given any cuts (c_i, c_j), we can easily construct T_{ij}. For example, we can set the left most leaf value in T_{ij} as L_i(c_i, c_j).a.L_w(c_i, c_j).a. It is easy to see that with those bookkeeping data structures, we can reduce the complexity of building predictors to O(1).

4.1.3 Calculating RSS

In this section, we show that calculating RSS for T_{ij} can be very efficient. Consider the definition of RSS. Let T_{ij}.r denote the prediction value on region r, where r \in \{a, b, c, d\}.

\[
RSS = \sum_{k=1}^{N} (y_k - T_{ij}(x_k))^2
\]  

(8)

In practical implementation, we only need to care about \sum_{r}(T_{ij}.r) L_i.r + \sum_{r}(T_{ij}.r) L_w.r since we are only interested in relative ordering of RSS, and it is easy to see the complexity of computing RSS for T_{ij} is O(1).

4.1.4 Complexity Analysis

For each pair (x_i, x_j), computing the histograms and cumulative histograms needs to scan through the data and therefore its complexity is O(N). Constructing the lookup tables takes O(d_i d_j + N) time. Thus, the time complexity of FAST is O(d_i d_j + N) for one pair (x_i, x_j). Besides, since we need to store d_i-by-d_j matrices for each pair, the space complexity is O(d_i d_j).

For continuous features, d_i d_j can be quite large. However, we can discretize the features into b equi-frequency bins. Such feature discretizing usually does not hurt the performance of regression tree [17]. As we will see in Section 5, FAST is not sensitive to a wide range of bs. Therefore, the complexity can be reduced to O(b^2 + N) per pair when we...
discretize features into $b$ bins. For small $bs$ ($b \leq 256$), we can quickly process each pair.

## 4.2 Two-stage Construction

With FAST, we can quickly rank of all pairs in $Z$, the remaining pair set, and add the best interaction to the model. However, refitting the whole model after each pair is added can be very expensive for large high-dimensional datasets. Therefore, we propose a two-stage construction approach.

1. In Stage 1, build the best additive model $F$ in $H^1$ using only one-dimensional components.

2. In Stage 2, fix the one-dimensional functions, and build models for pairwise interactions on residuals.

### 4.2.1 Implementation Details

To scale up to large datasets and many features, we discretize the features into 256 equi-frequency bins for continuous features. We find such feature discretization rarely hurts the performance but substantially reduces the running time and memory footprint since we can use one byte to store a feature value. Besides, discretizing the features removes the sorting requirement for continuous features when searching for the best cuts in the space.

Previous research showed that feature shaping using gradient boosting [10] with shallow regression tree ensembles can achieve the best accuracy [19]. We follow similar approach (i.e., gradient boosting with shallow tree-like ensembles) in this work. However, a regression tree is not the ideal learning method for each component for two reasons. First, while regression trees are good as a generic shape functions learning method for each component for two reasons. First, we develop for FAST for fast search of those three cuts. Figure 3 shows an example of computing the leaf values given $c_i$, $c_j$, and $c$. Similarly, we can quickly compute the $RSS$ given any combination of 3 cuts once the leaf values are available, just as we did in Section 4.1.3 and therefore it is very fast to search for the best combination of cuts in this space. Similarly, we search for the best combination of 3 cuts with 1 cut on $x_i$ and 2 cuts on $x_i$ and pick the better model with lower $RSS$. It is easy to see the complexity is $O(N + b^2)$, where $b$ is the number of bins for each feature and $b = 256$ in our case.

### 4.2.2 Further Relaxation

For large datasets, even refitting the model on selected pairs can be very expensive. Therefore, we propose to use the ranking of FAST right after Stage 1, to select the top-$K$ pairs to $S$, and fit a model using the pairs in $S$ on the residual $R$, where $K$ is chosen according to computing power.

### 4.2.3 Diagnostics

Models that combine both accuracy and intelligibility are important. Usually $S$ will still be an overcomplete set. For intelligibility, once we have learned the best model in $H$, we would like to rank all terms (one- and two-dimensional components) so that we can focus on the most important features, or pairwise interactions. Therefore, we need to assign weights for each term. We use $\sqrt{E[f_u^2]}$, the standard deviation of $f_u$ (since $E[f_u] = 0$), as the weight for term $u$. Note this is a natural generalization of the weights in the linear models; this is easy to see since $f_i(x_i) = w_i x_i$, $\sqrt{E[f_u^2]}$ is equivalent to $|w_i|$ if features are normalized so that $E[x_i^2] = 1$.

## 5. EXPERIMENTS

In this section we report experimental results on both synthetic and real datasets. The results in Section 5.1 show GA^2M learns models that are nearly as accurate as full-complexity random forest models while using terms that depend only on single features and pairwise interactions and thus are intelligible. The results in Section 5.2 demonstrate that FAST finds the most important interactions of $O(n^2)$ feature pairs to include in the model. Section 5.3 compares the computational cost of FAST and GA^2M to competing methods. Section 5.4 briefly discusses several important de-
sign choices made for FAST and GA²M. Finally, Section 5.5 concludes with a case study.

5.1 Model Accuracy on Real Datasets
We run experiments on ten real datasets to show the accuracy that GA²M can achieve with models that depend only on 1-d features and pairwise feature interactions.

5.1.1 Datasets
Table 1 summarizes the 10 datasets. Five of the datasets are regression problems: “Delta” is the task of controlling the ailerons of an F16 aircraft; “CompAct” is a regression dataset from Delve repository that describes the state of multifuser computers; “Pole” describes a telecommunication dataset from Delve repository that describes the state of the ailerons of an F16 aircraft; “Physics” dataset is from the KDD Cup 2004. Although it is possible that higher

We compare GA²M to linear/logistic regression, feature shaping (GAMs) without interactions, and full-complexity random forests. For regression problems we report root mean squared error (RMSE) and for classification problems we report 0/1 loss. To compare results across different datasets, we normalize results by the error of GAMs on each dataset. For all experiments, we train on 80% of the data and hold aside 20% of the data as test sets.

In addition to FAST, we also consider three baseline methods on five high dimensional datasets, i.e., GA²M Rand, GA²M Coef and GA²M Order. GA²M Rand means we add the same number of random pairs to GAM. GA²M Order and GA²M Coef use the weights of 1-d features in GAM to propose pairs; GA²M Order generates pairs by the order of 1-d features and GA²M Coef generates pairs by the product of weights of 1-d features.

The regression and classification results are presented in Table 2 and Table 3. As expected, the improvement over GAM is substantial: on average feature shaping reduces RMSE 34% on the regression problems, and reduces 0/1 loss 44% on the classification problems. What is surprising, however, is that by adding shaped pairwise interactions to the models, GA²M FAST substantially closes the accuracy gap between uninterpretable full-complexity models such as random forests and GAMs. On some datasets, GA²M FAST even outperforms the best random forest model. Also, none of the baseline methods perform as well as comparably GA²M FAST.

5.2 Detecting Feature Interactions with FAST
In this section we evaluate how accurately FAST detects feature interactions on synthetic problems.

5.2.1 Sensitivity to the Number ofBins
We compare synthetic function generator in 10 to generate random functions. Because these are synthetic function, we know the ground truth in-
teracting pairs and use average precision (area under the precision-recall curve evaluated at true points) as the evaluation metric. We vary $b = 2, 4, ..., 256$ and the dataset size $N = 10^2, 10^3, ..., 10^6$. For each fixed $N$, we generate datasets with $n$ features and $k$ higher order interactions $x_u$, where $|u| = |1.5 + r|$ and $r$ is drawn from an exponential distribution with mean $\lambda = 1$. We experiment with two cases: 10 features with 25 higher order interactions and 100 features with 1000 higher order interactions.

Figure 3 shows the mean average precision and variance for 100 trials at each setting. As expected, average precision increases as dataset size increases, and decreases as the number of features increases from 10 (left graph) to 100 (right graph). When there are only 10 features and as many as $10^6$ samples, FAST ranks all true interactions above all non-interacting pairs (average precision = 1) in most cases, but as the sample size decreases or the problem difficulty increases average precision drops below 1. In the graph on the right with 100 features there are 4950 feature pairs, and FAST needs large sample sizes ($10^6$ or greater) to achieve average precision above 0.7, and as expected performs poorly when there are fewer samples than pairs of features.

On these test problems the optimal number of bins appears to be about $b = 8$, with average precision falling slightly for number of bins larger and smaller than 8. This is a classic bias-variance tradeoff: smaller $b$ reduces the chances of overfitting but at the risk of failing to model some kinds of interactions, while large $b$ allows more complex interactions to be modeled but at the risk of allowing some false interactions to be confused with weak true interactions.

5.2.2 Accuracy

The previous section showed that FAST accurately detects feature interactions when the number of samples is much larger than the number of feature pairs, but that accuracy drops as the number of feature pairs grows comparable to and then larger than the number of samples. In this section we compare the accuracy of FAST to the interaction detection methods discussed in Section 5.2. For ANOVA, we use R package mgcv to compute $p$-values under a Wald test [23]. For PDF, we use RuleFit package and we choose $m = 100, 200, 400, 800$, where $m$ is the sample size that trades off efficiency and accuracy [7]. Grove is available in TreeExtra package [8].

Here we conduct experiments on synthetic data generated by the following function [14, 22].

$$F(x) = \pi^{x_1x_2} \sqrt{2\pi} x_3 - \sin^{-1}(x_4) + \log(x_3 + x_5) - \frac{x_9}{x_{10}} \sqrt{\frac{x_7}{x_8}} - x_2x_7$$

Variables $x_4, x_5, x_8, x_{10}$ are uniformly distributed in $[0.6, 1]$ and the other variables are uniformly distributed in $[0, 1]$. We use 10,000 points for these experiments. Figure 5(a) shows the average precision of the methods. On this problem, Grove and ANOVA methods are accurate and rank all 11 true pairs in the top of the list. FAST is almost as good and correctly ranks the top ten pairs. The other methods are significantly less accurate than Grove, ANOVA, and FAST.

To understand why FAST does not pick up the 11th pair, we plot heat maps of the residuals of selected pairs in Figure 6. $(x_1, x_2)$ and $(x_2, x_7)$ are two of the correctly ranked true pairs, $(x_1, x_7)$ is a false pair ranked below the true pairs FAST detects correctly but above the true pair it misses, and $(x_8, x_{10})$ is the true pair FAST misses and ranks below this false pair. The heat maps show strong interactions are easy to distinguish, but some false interactions such as $(x_1, x_7)$ can have signal as strong as that of weak true interactions such as $(x_8, x_{10})$. In fact, Sorokina et al. found that $x_8$ is a weak feature, and do not consider pairs that use $x_8$ as interactions on 5,000 samples [22], so we are near the threshold of detectability of $(x_8, x_{10})$ going from 5,000 to 10,000 samples.

5.2.3 Feature Correlation and Spurious Pairs

If features are correlated, spurious interactions may be detected because it is difficult to tell the difference between a true interaction between $x_1$ and $x_2$ and the spurious interaction between $x_1$ and $x_3$ when $x_3$ is strongly correlated with $x_2$: any interaction detection method such as FAST that examines pairs in isolation will have this problem. With GA^2M, however, it is fine to include some false positive pairs because GA^2M is able to post-filter false positive pairs by looking at the term weights of shaped interactions in the final model.

To demonstrate this, we use the synthetic function in Equation 10 but make $x_6$ correlated to $x_1$. We generate 2 datasets, one with $p(x_1, x_6) = 0.5$ and the other with $p(x_1, x_6) = 0.95$, where $p$ is the correlation coefficient. We run FAST on residuals after feature shaping. We give the top 20 pairs found by FAST to GA^2M, which then uses gradient boosting to shape those pairwise interactions. Figure 7 illustrates how the weights of selected pairwise interactions evolve after each step of gradient boosting. Although the pair $(x_2, x_6)$ can be incorrectly introduced by FAST because of the high correlation between $x_1$ and $x_6$, the weight on this false pair decreases quickly as boosting proceeds, indicating that this pair is spurious. This not only allows the model trained on the pairs to remain accurate in the face of spurious pairs, but also reduces the weight (and ranking) given to this shaped term so that intelligibility is not be hurt by the spurious term.
5.4 Design Choices

An alternate to interaction detection that we considered was to build ensembles of trees on residuals after shaping the individual features and then look at tree statistics to find combinations of features that co-occur in paths more often than their independent rate warrants. By using 1-step lookahead at the root we also hoped to partially mitigate the myopia of greedy feature installation to make interactions more likely to be detected. Unfortunately, features with high “co-occurrence counts” did not correlate well with true interactions on synthetic test problems, and the best tree-based methods we could devise did not detect interactions as well as FAST, and were considerably more expensive.

5.5 Case Study: Learning to Rank

Learning-to-rank is an important research topic in the data mining, machine learning and information retrieval communities. In this section, we train intelligible models with shaped one-dimensional features and pairwise interactions on the “MSLR10k” dataset. A complete description of features can be found in [3]. We show the top 10 most important individual features and their shape functions in first two rows of Figure 9. The number above each plot is the weight for the corresponding term in the model. Interestingly, we found BM25 [20], usually considered one of the more powerful features for ranking, ranked 79th (BM25_url) in the list after shaping. Other features such as IDF (inverse document frequency) enjoy much higher weight in the learned model.

The last two rows of Figure 9 show the 10 most important pairwise interactions and their term strengths. Each of these plots shows a clear interaction that could not be modeled by independent linear terms. The non-linear shaping of the individual features in the top plots and the pairwise interactions in the bottom plots are intelligible to experts and feature engineers, but would be well hidden in full-complexity models.

6. CONCLUSIONS

We present a framework called GA²M for building intelligible models with pairwise interactions. Our novel method called FAST efficiently measures the strength of all interactions.
